1. Introduction

Waste rock stockpiles exposed to atmospheric conditions from the natural environment may pose environmental risks to surface and groundwater quality due to potential metal leaching (ML) and acid rock drainage (ARD) from the mine development phase through post-closure. When the risks of groundwater contamination are significant, it is possible to put in place mitigation measures (e.g., a geomembrane liner under the pile) in order to limit infiltration.

This study was conducted to determine if the investment in such mitigation measures is justified in the case of the waste rock stockpiles currently being designed for the Corvette Lithium Project. Vision Geochemistry Ltd. (Vision) was retained by BBA Inc. (BBA) to investigate this question within the framework of the Preliminary Economic Assessment (PEA) conducted by BBA.

Prior to BBA and Vision's involvement in economical and geochemical studies, several total contents analyses of the waste rock material using the Na-peroxide fusion method were carried out by Innova Lithium Inc. (Innova), as part of the exploration drilling program, in order to collect geochemical data and facilitate future geometallurgical and environmental work. This dataset, herein referred to as the drillhole database (DHDB), containing 4,968 samples (at the time the study was being conducted) has been utilized by BBA/Vision to design a geochemical characterization program involving the static and kinetic analysis of a selection of waste rock samples of different lithologies.

This program was designed to identify chemicals of potential concern (COPC) for the Corvette Lithium Project. The geochemical characterization program has highlighted arsenic as a primary potential risk with regard to exceedance of the groundwater protection guidelines (resurgence in surface water criteria of 0.34 mg/l) provided by the *Ministère de l'Environnement, de la Lutte contre les Changements Climatiques, de la Faune et des Parcs* (MELCCFP). Although enriched arsenic contents and leaching potential were observed among all lithology types, the ultramafic material was identified as raising significantly more concern for environmental risk.

Considering their relative toxicity levels, concentrations of all other parameters measured in the geochemical characterization program do not justify the same modeling effort as for arsenic.

The present report incorporates the information generated from the previous report, titled *Analysis and Interpretation of the CV5 Static and Kinetic Geochemistry Characterization Results* (BBA/Vision, 2024), to derive source terms for geochemical modelling of waste rock stockpiles. The source terms serve as model inputs along with scaling factors to simulate numerical models that further characterize the risk associated with arsenic leaching in waste rock stockpiles and, therefore, support engineering designs for surface water and groundwater management.

1.1. Objectives and approach

Following the background highlighted above, the principal objectives of the present study are twofold and can be summarized as follows:

1. To evaluate the risk associated with arsenic leaching with regards to the MELCCFP groundwater protection guidelines (resurgence criteria) in the context of waste rock stockpiles operation; and
2. To guide engineering design and highlight technical practices that will support arsenic leaching mitigation and facilitate the development of the project.

The approach chosen and developed throughout this study can be summarized according to the following 3-step sequence:

1. Establishing a correlation between the arsenic leaching rates measured from the kinetic tests, and the arsenic contents provided by the DHDB, and using this correlation to derive arsenic source terms for all samples of the DHDB.
2. Developing and applying scaling factors to adjust the calculated leaching rates from kinetic testing to field scale.
3. Building a 1D geochemical model of the pile with random distribution of the lithologies and arsenic contents, and testing different deposition scenarios in order to investigate the risk associated with arsenic leaching from the waste rock stockpiles.

2. Model design

The purpose of this section is to detail the data that was utilized and the assumptions that were made in the elaboration of the model designed to investigate the potential risk associated with the leaching of arsenic from the waste rock material.

2.1. Conceptual model and hypotheses

The model corresponds to a preliminary investigation to characterize the behaviour of waste rock stockpiles regarding arsenic leaching. Some assumptions are subject to refinement as the understanding of the physicochemical characteristics of the material and of the field conditions progresses. The model design relies on four (4) principal hypotheses:

1. Steady state is assumed. The effect of seasonality on geochemical reactive transport is neglected in the current model. The rationale supporting this hypothesis is that the large size of the pile and the relatively slow movement of water within the waste rock matrix tend to average out the influence of climate fluctuations such as the alternance of wet and dry periods and the temperature variations on the arsenic concentration of the leachate reaching the bottom of the pile.
2. Physical properties such as particle size distribution, temperature, and hydraulic conductivity are considered homogeneous across the pile, and the lithologies and associated arsenic leaching rates are randomly distributed across the model. In addition to being a simplifying hypothesis, the random distribution of the geochemical properties allows for a statistical analysis of the influence of the placement of the waste rock materials of different lithologies inside the pile on arsenic leachates concentration.
3. The mobilization of arsenic is assumed to be dominated by oxidative processes. In practice, this suggests that the load of arsenic being mobilized per mass unit is solely time-dependant and is not affected by the solid to liquid ratio, as opposed to mere dissolution. This hypothesis is supported by the fact that, following a few initial flushes, the HCT results showed steady state release of arsenic over time at concentrations significantly below saturation.
4. The model only assumes 1D vertical transport and lateral flow is ignored. This hypothesis simplifies the modeling effort and is supported by the fact that hydraulic conductivity of waste rock is relatively high, and allows the material to drain rapidly, thus preventing a significant accumulation of water above natural ground surface. This is a conservative assumption as the emergence of elevated water table conditions would impede oxidation processes and limit the mobilization of arsenic. The infiltration rate was assumed to range between 600 and 700 mm per year. For reference, the average annual precipitation at La Grande 1 Dam meteorological station is 697.2 mm (approximately 300 km west of the project's site).

2.2. Lithologies and arsenic mobilization

Static testing, as well as kinetic testing involving seventeen (17) humidity cell tests (+1 duplicate), were conducted on waste rock samples of different lithologies, and of a wide range of arsenic contents, in order to assess the leaching potential of the material. The results of the kinetic tests are discussed in a previous report titled *Analysis and Interpretation of the Analysis and Interpretation of the CV5 Static and Kinetic Geochemistry Characterization Results* (BBA/Vision, 2024).

The graphic presented in Figure 1 shows that there is a correlation ($R^2 = 0.66$) between the arsenic content of the waste rock materials provided by the Na-peroxide fusion method, and the leaching rate measured through HCT. The equation provided by the regression line of the correlation is:

As leaching rate (mg/kg/week) = 8.62×10^{-4} ($week^{-1}$) x As content (mg/kg)

This equation can be utilized in combination with the Na-peroxide fusion data to derive arsenic leaching rates for all samples of the DHDB.

Additionally, Na-peroxide fusion measurements, and both static and kinetic leaching tests results, have allowed the identification of the ultramafic waste rock material as generally more enriched with arsenic, and equally more prone to arsenic leaching and potential exceedances of the MELCCFP resurgence criterion. This observation has highlighted the importance of developing strategies in order to mitigate the impact associated with this particular waste rock type.

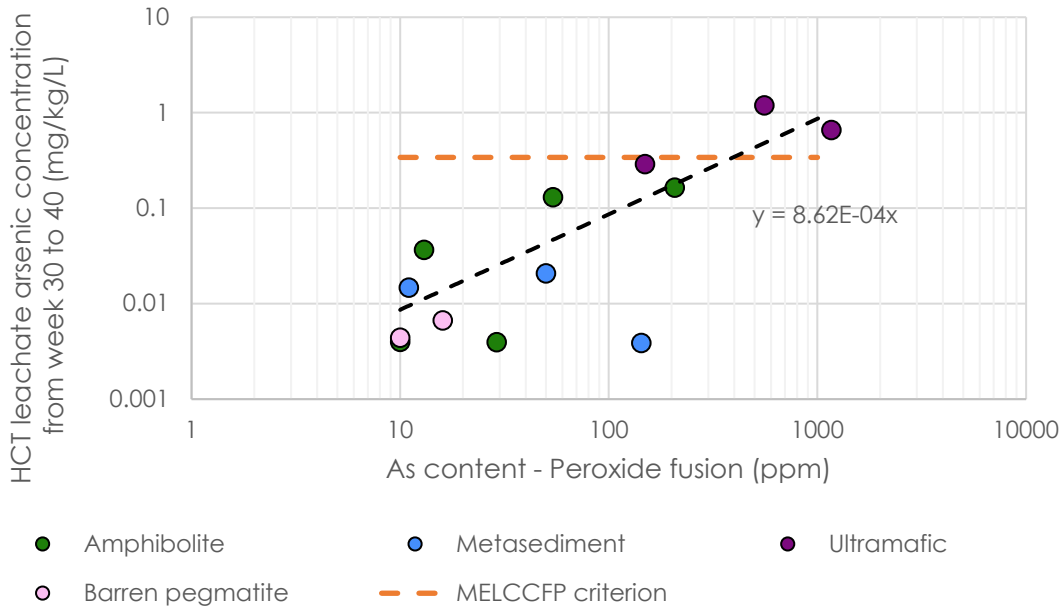

Figure 1: Graphic representation of the correlation between arsenic content and average HCT leaching rate from Week 30 and Week 40

2.4. Source terms scaling factors

The testing conditions in which the HCT leaching rates are measured in the laboratory are not representative of the field. Three (3) principal phenomena are generally recognized as explaining discrepancies between geochemical behaviour within a waste rock stockpile and HCT. These include particle size distribution (PSD), temperature, and hydraulic isolation. Scaling factors are typically employed to adjust the leaching rate measured at the laboratory and derive source terms that will be more representative of the field conditions.

For the model used in this study, the waste rock pile leaching rate was calculated using the following **Equation 1** (Kempton, 2012):

$$R_{WRP} = R_{HCT} \times S_{PSD} \times S_{Temp.} \times S_{HI} \qquad \textbf{Equation 1}$$

In which:

- R_{WRP} is the leaching rate within the waste rock pile (mg/kg/week)
- R_{HCT} is the leaching rate within the HCT (mg/kg/week)
- S_{PSD} is the PSD scaling factor (unitless)
- $S_{Temp.}$ is the temperature scaling factor (unitless)
- S_{HI} is the hydraulic isolation scaling factor (unitless)

2.4.1. Particle size distribution

At a mine site, the PSD of waste rock materials can typically range from the micrometric to metric scale. When tested in a laboratory, however, these materials must be screened for sake of standardization and practicality. Nonetheless, the surface/volume ratio of small particles is greater than that of bigger particles, and the leachability of a material is highly dependant on its specific surface area. For representativeness, the waste rock loading rate calculated in laboratory conditions must thus be scaled to the field conditions. In HCT, particles are screened and/or crushed to reach a maximum of 6.3 mm in diameter.

A literature review has allowed Stockwell et al. (2006) to argue that more than 80% of the geochemical weathering originates from particles below 25 mm in diameter, and that this fraction represents 10-40% of the total; depending on the blasting method and rock type.. Additionally, igneous rocks and highly metamorphized sediments, such as those of the Corvette Lithium Project, are known to generate smaller proportions of fines when blasted (Dawson, 1994). For instance, the Goliath project, for which waste rock lithology is primarily composed of a

combination of granite, metasediment and shales, presents approximately 5% of particles with a diameter below 2.5 mm (Ecometrix_Inc., 2014). A relatively conservative scaling factor of 10% was selected for the present modelling effort.

2.4.2. Temperature

Mineralogical analysis conducted on waste rock samples showed that arsenic was present within sulfidic mineral phases (arsenopyrite, gersdorffite, niccolite (BBA/Vision, 2024)). Chemical reaction rates, resulting from the oxidation of sulfidic minerals, are affected by temperature as described by the Arrhenius Law. **Equation 2**, derived from the Arrhenius law, allows to determine the reaction rate scaling factor:

$$SF_{Temp} = \mathrm{Exp}\left(\frac{E_a(T_{Field} - T_{Lab})}{R T_{Field} T_{Lab}}\right)$$ **Equation 2**

In which:

- E_a is the activation energy of the pyrite oxidation reaction likely responsible for releasing metals (80 kJ/mol; (Nicholson, et al. 1988))
- T_{Field} and T_{Lab} are the average field and laboratory temperature, respectively (K)
- R is the universal gas constant (8.314 J/mol/K)

A conservative average temperature of -2 °C, obtained from tele-detection method (Wang et al., 2013), was utilized to represent Corvette site conditions, and an estimated laboratory temperature of 22.5 °C was chosen for the HCT. These values provided temperature scaling factor was 0.05.

2.4.3. Hydraulic isolation

The water contact factor is related to the internal structure of the stockpiles, having large variability in unsaturated hydraulic conductivity. The contact factor accounts for a reduction in solute leaching because some portions of the piles are expected to become hydraulically isolated through the development of preferential flow paths and will not be flushed by pore water as often as HCT. A literature review conducted on geochemical modeling reports showed that this factor ranges widely from 0.03 and 0.77, although values between 0.10 and 0.20 are most common. Moreover, this factor is also influenced by the small proportion of fines, as water in heterogeneous media tends to travel preferentially within finer particles. The relative scarcity of

fines may therefore lead to the hydraulic isolation of numerous material clusters. A hydraulic isolation factor of 0.10 was selected in this modeling study.

2.4.4. Calculation of concentrations

The concentrations of arsenic (mg/l) inside the pile or at the bottom of the pile is estimated from:

- Contaminants loads (mg) calculated from the loading rates (Section 2.4.1) for a given mass of material and a given period of time;
- Percolation water volumes (m^3) corresponding to the precipitation reaching the surface of the considered mass of material (m^2) and the precipitation volume for the considered period (mm/m^2, or l/m^2).

2.5. Tested scenarios

As mentioned in Section 2.2, the ultramafic lithology was identified as more prone to higher arsenic content and arsenic leaching. Based on this observation, three (3) scenarios were developed in order to examine possible mitigation measures that would minimize the reliance of the engineering design to development of mitigation measures such as large-scale geomembrane liner for all waste rock stockpiles. The following three (3) scenarios have been considered:

Scenario I: Co-deposition of all lithologies in a single waste rock pile. This scenario corresponds to a base case with no particular effort allocated to the differential management of the various waste rock lithologies (no segregation). Relative proportion of each lithology is provided in Table 1.

Scenario II: Complete segregation of the ultramafic waste rock material and placement of waste rock in different piles. This scenario corresponds to an ideal case which corresponds to the best outcome that can be achieved when attempting to segregate the ultramafic material from other lithologies. In this scenario, all the ultramafic will be sent to the same stockpile and other stockpiles will contain no ultramafic material.

Scenario III: Segregation of 85% of the ultramafic waste rock material and placement of waste rock in different piles. This scenario corresponds to a more realistic case simulated to evaluate the risk associated with residual ultramafic material within the waste rock pile composition. In this scenario, 15% of the ultramafic rock will be sent to stockpiles distinct from the stockpile expected for ultramafic rock storage only.

The tested scenarios and the corresponding lithological composition of the waste rock placed in the pile for each scenario is summarized in Table 1.

Table 1: Lithological composition of the waste rock material of the pile in each scenario

Scenario	Amphibolite	Barren Pegmatite	Metasediment	Ultramafic
I - Co-disposition	55.6%	3.1%	31.6%	9.6%
II - Complete segregation	61.5%	3.5%	35.0%	0.0%
III - 85% segregation	60.7%	3.4%	34.5%	1.4%

3. Modeling results and interpretation

As specified in the model design section, three (3) modeling scenarios were evaluated: (I) the co-deposition of all waste rock lithologies, (II) the complete segregation of the ultramafic lithology, (III) the segregation of 85% of the ultramafic lithology.

Figure 2 displays typical vertical profiles of the percolating water's arsenic concentration corresponding to one (1) iteration of the model for each of the tested scenarios. These profiles show that the arsenic concentrations increase gradually with depth as the water progressively dissolves the arsenic available at the surface of the rock. Although the arsenic concentration is proportional to depth for the three scenarios, the progression appears somewhat irregular due to the random distribution of the lithologies and corresponding arsenic content percentile values.

Scenario I displays the highest concentrations throughout the profile and even exceeds the MELCCFP arsenic resurgence criterion of 0.34 mg/l at approximately 106 m below the surface of the pile, while other scenarios remain well below the criterion with 0.14, and 0.19 mg/l at the bottom of the pile for Scenarios II, and III, respectively. The gradation of the arsenic concentration with regards to the ultramafic proportion in the waste rock composition confirms the importance of this lithology as a main driver of arsenic mobilization.

Considering that the percolating water's arsenic concentrations increase with depth, the elevation of the pile will have an important impact on the quality of the leachates reaching the bottom of the pile. Consequently, the two (2) principal outputs considered as part of this analysis are (1) the arsenic concentration of the leachates reaching the bottom of a 125 m pile, and (2) the cut-off elevation corresponding to the maximum pile elevation allowing for the arsenic concentration of the percolating waters to remain below the MELCCFP resurgence criterion (0.34 mg/l).

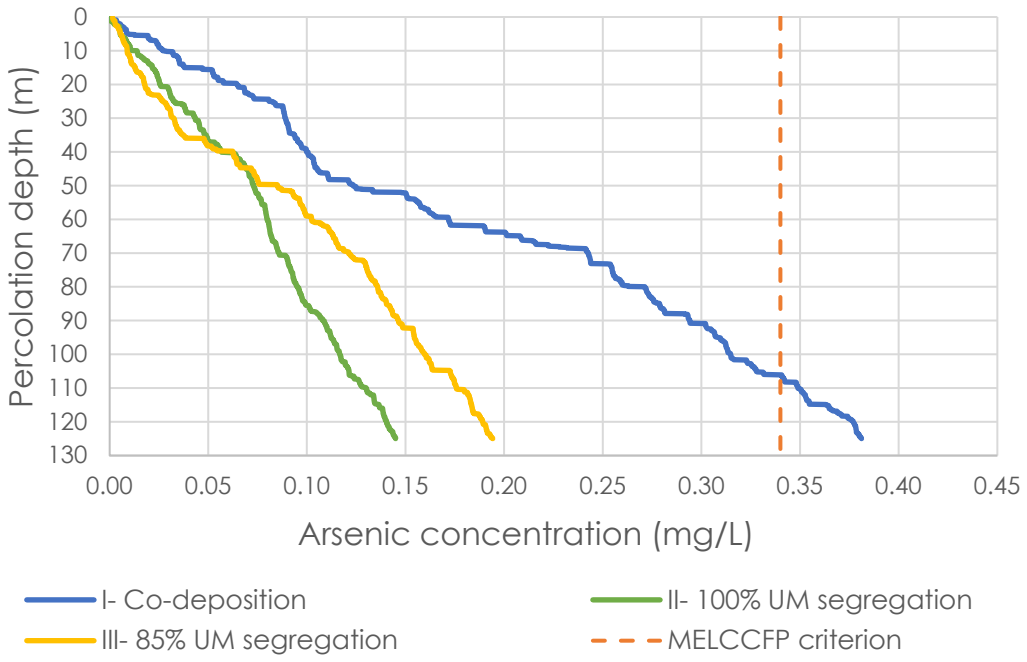

Figure 2: Typical vertical profiles of arsenic concentrations in percolating waters for each of the modeled scenarios

3.1. Analysis of modeling results per lithology type

Based on the model hypotheses it could be determined that in order to prevent arsenic leaching conditions at the bottom of a 125 m pile, the average arsenic leaching rate of the material within the pile should not exceed approximately 1.82×10^{-5} mg/kg/week. By combining the correlation that was derived between the Na-peroxide fusion arsenic contents and HCT leaching rates, and the scaling factors that were developed, it could be estimated that an average leaching rate of 1.82×10^{-5} mg/kg/week corresponds, approximately, to an average arsenic content cut-off of 40 ppm (or mg/kg) for a pile containing various lithologies. In other terms, a pile of 125 m of elevation should generate percolating waters arsenic concentrations superior to 0.34 mg/l if the average arsenic content is superior to 40 mg/kg.

The comparison between arsenic content distribution for the various lithologies presented in Figure 3 shows that the ultramafic material stands-out from the other lithologies with contents exceeding 133 ppm starting from the 50th percentile, as opposed to 8 ppm for the barren pegmatite, and 2.5 ppm for the amphibolites and metasediments. The orange dotted line indicates the pile's average arsenic content value above which the concentration of the water reaching the bottom of a 125 m high pile may exceed the 0.34 mg/l criterion , according to the

modeling hypotheses. It appears that the ultramafic material exceeds the cut-off value around the 38th percentile while amphibolites, the metasediment and the barren pegmatite exceed it around the 88th, 92nd, and 97th percentile, respectively. It should be stressed, however, that the materials above the line do not necessarily represent a fundamental concern on their own, but rather constitute a risk if stacked high enough to allow for arsenic to accumulate sufficiently within the leachate.

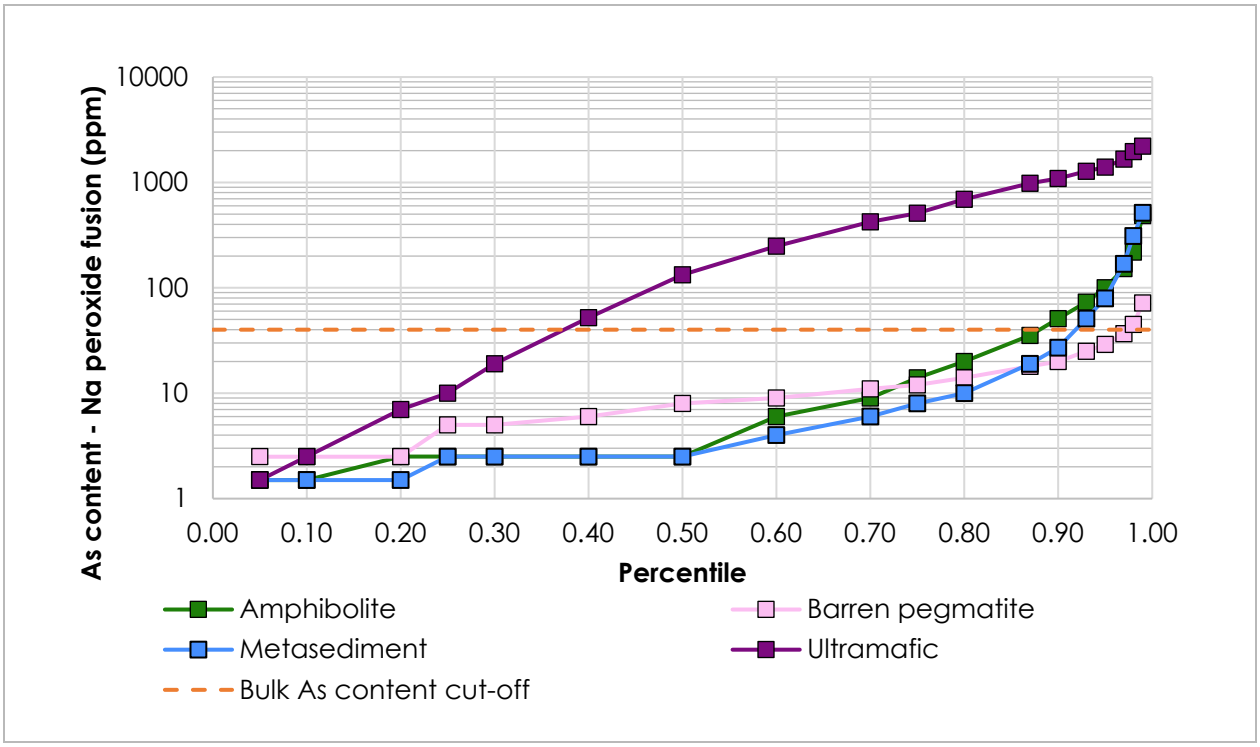

Figure 3: Graphic representation of arsenic content distribution as a function of the arsenic content percentile for each waste rock lithology

Plotting the corresponding cut-off elevation as a function of the arsenic content percentile (Figure 4) shows that the ultramafic material of the 74th arsenic content percentile (or an average content of ± 500 mg/kg) and higher should not be stacked as a pile of 10 m and higher. However, in the case of the amphibolite and the metasediment materials, only the upper percentile (99th and higher) should not be stacked higher than 10, and 9 m, respectively. The barren pegmatite lithology appears to pose very limited concern as the upper percentile (99th percentile) can still be stacked as high as 67 m.

Consequently, only piles showing high proportion of ultramafic waste rock are likely to contain high average As content and could, potentially, generate As leaching in exceedance of government criterion (resurgence.

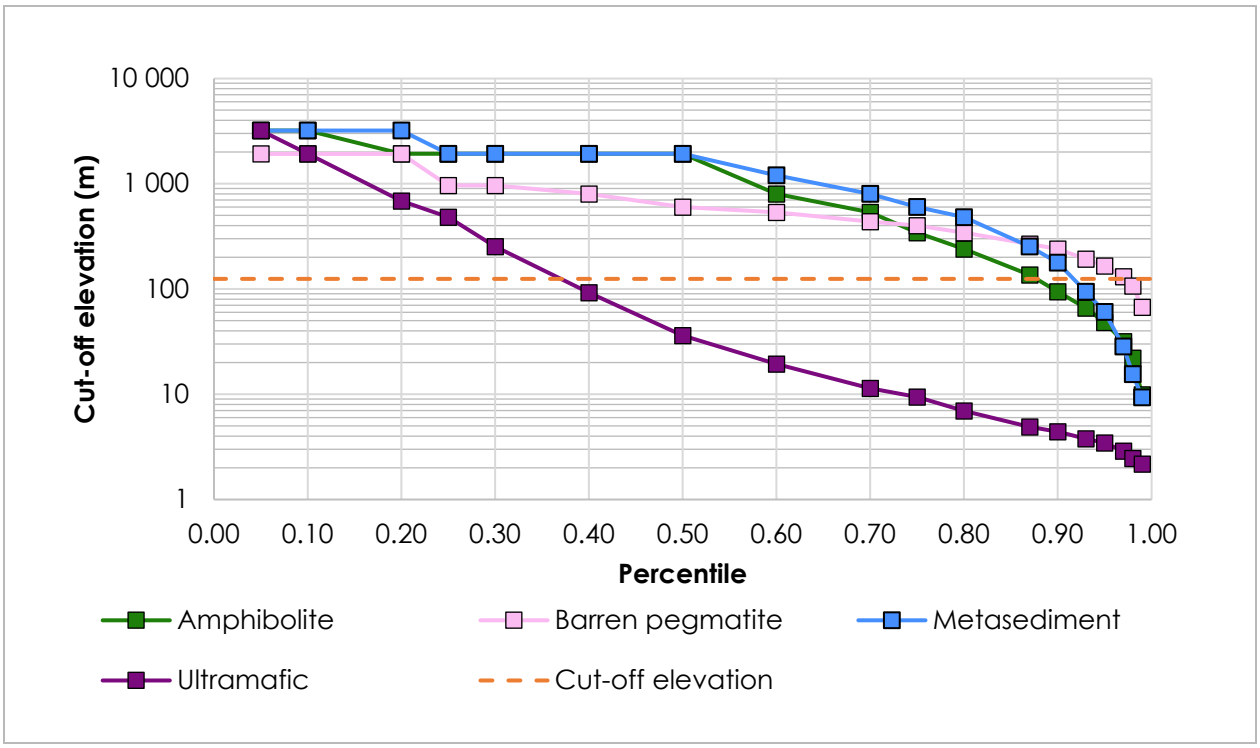

Figure 4: Graphic representation of cut-off elevation as a function of the arsenic content percentile for each waste rock lithology

Figure 5 displays the cut-off elevation considering the average arsenic leaching rate of each lithology type. The cut-off elevation for the ultramafic material is only 14 m, that is to say almost an order of magnitude below the current projections of a 125 m pile, thus confirming the concerns raised by this particular lithology. The cut-off elevation values for the other lithologies, on the other hand, are significantly higher, with 238 m for amphibolites, 314 m for barren pegmatite, and 267 m for the metasediments on average.

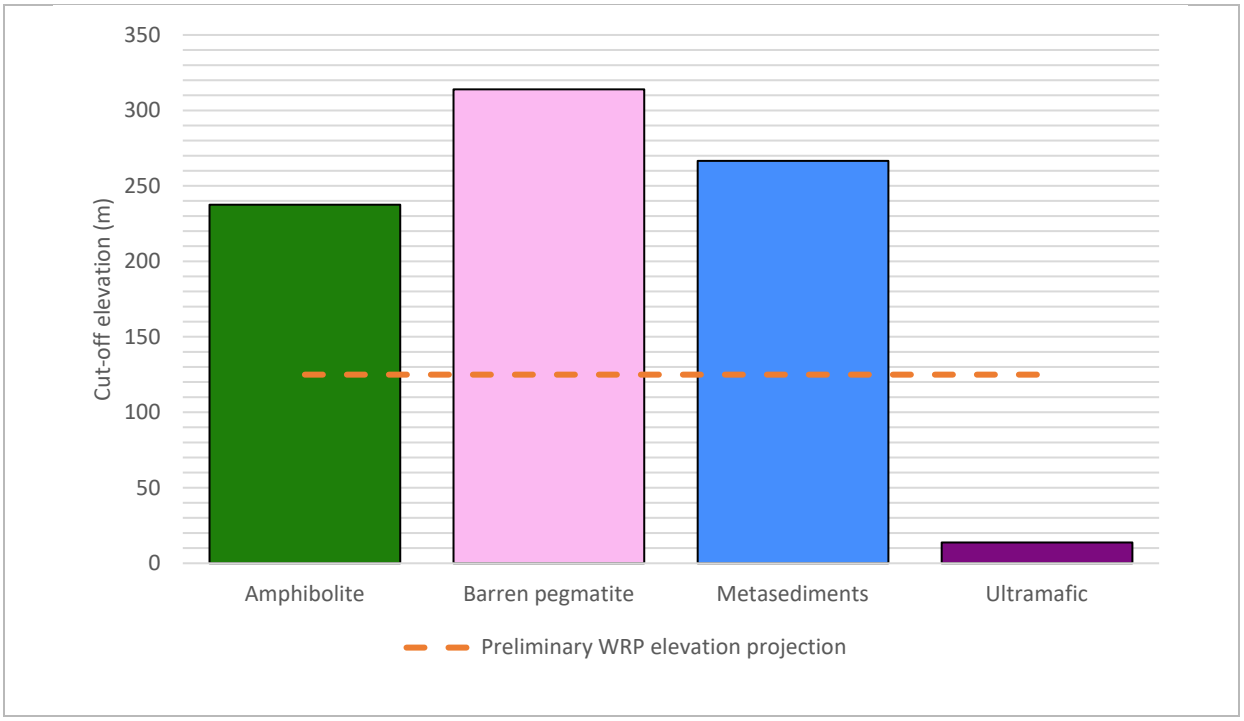

Figure 5: Average cut-off elevation estimated for each waste rock lithology

3.2. Probabilistic simulation results analysis

As specified in the model design section, a simulation comprising 1,000 iterations was run in order to investigate the risk associated with arsenic leaching for each of the tested scenarios, namely: (I) the co-deposition of all waste rock lithologies including all ultramafic (no segregation), (II) the complete segregation of the ultramafic lithology and the production of ultramafic free piles, (III) the segregation of 85% of the ultramafic lithology and the production of piles containing 15% of ultramafic .

The simulation results show that Scenario I presents, on average, concentrations at the bottom of the pile that are more than twice as important as for other scenarios with 0.43 mg/l, as opposed to 0.15, and 0.20 mg/l for Scenario II, and III, respectively (Figure 6a). Additionally, most iterations of Scenario I displayed bottom arsenic concentrations exceeding the MELCCFP resurgence criterion of 0.34 mg/l (orange dotted line) while all simulations from Scenario II and III remained significantly below criterion.

The arsenic concentration exceedances measured for Scenario I translate into pile cut-off elevation values that fall essentially below the projected pile elevation of 125 m (orange dotted line, Figure 6b) with 101 m on average and a value as low as 58 m for one occurrence. The other scenarios, on the other hand, present cut-off elevation values significantly above the 125 m mark with average values of 286 m, and 220 m for Scenarios II and III, respectively.

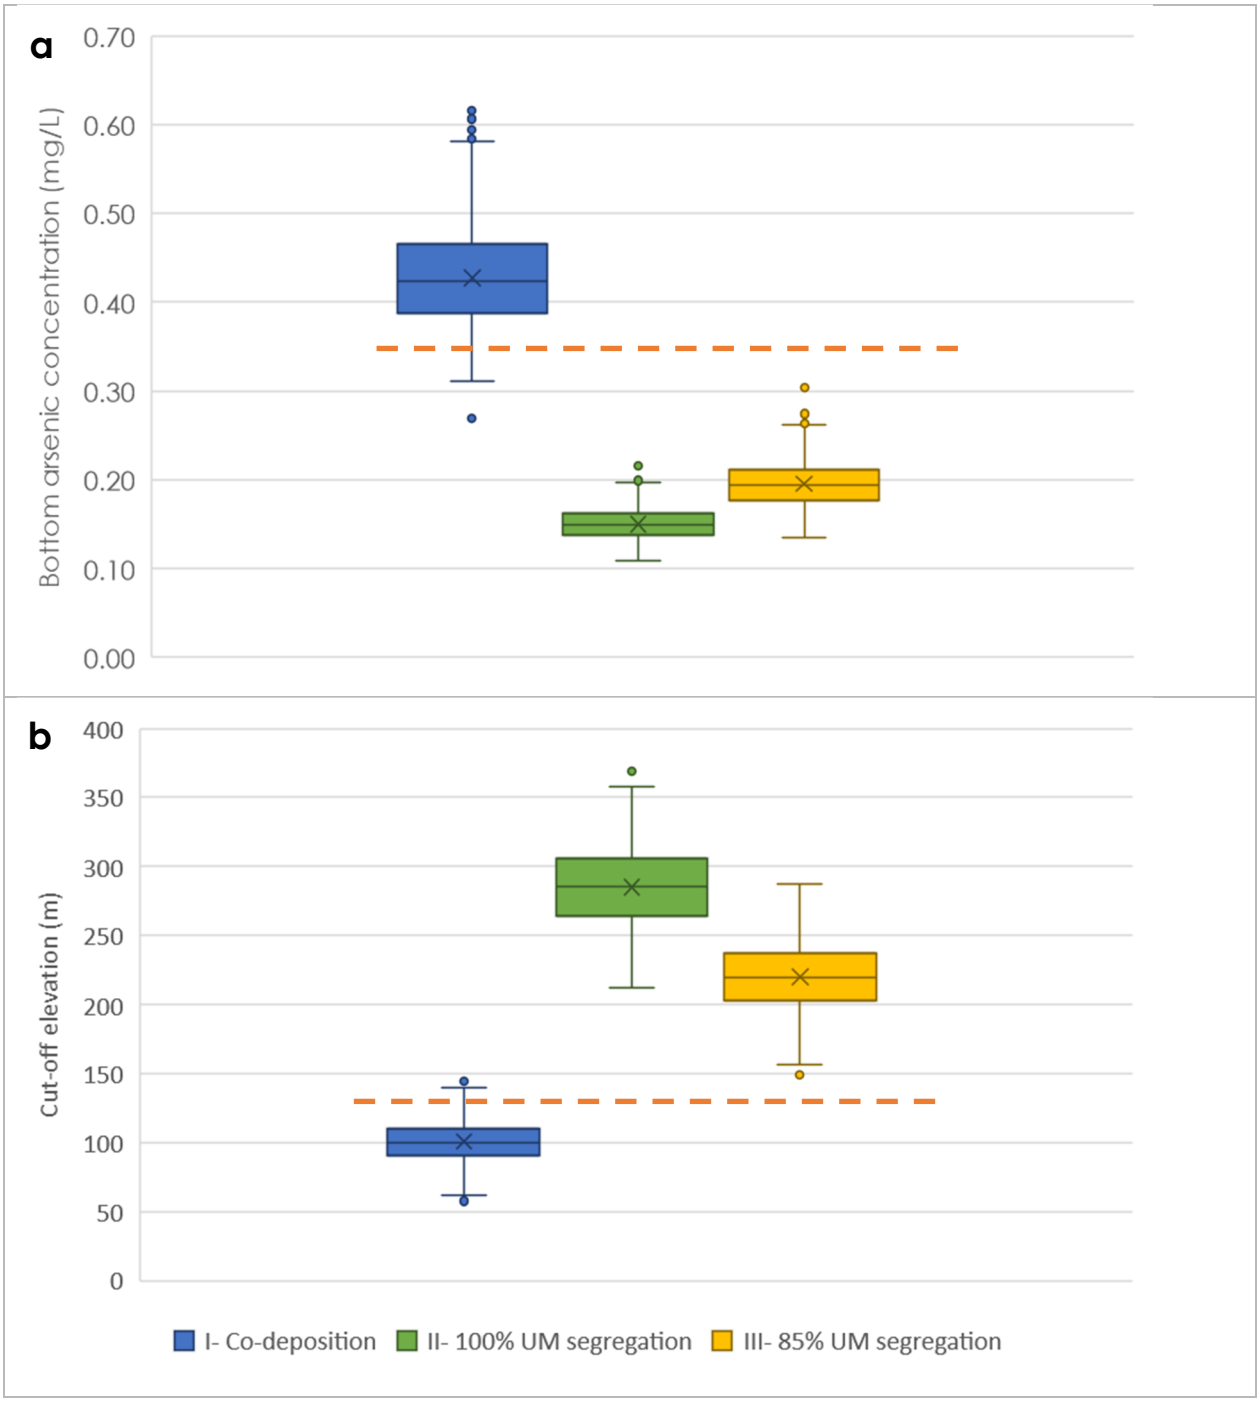

Figure 6: Statistical distribution of arsenic concentration at the bottom of the pile and cut-off elevation for the different tested scenarios

The 2D representations of the 1D modelling results presented in Figure 7, Figure 8 and Figure 9 illustrate typical repartitions of the leachate arsenic concentrations within a 125 m pile for the three (3) tested scenarios.

The profile generated for Scenario I (no segregation) reveals that arsenic concentrations tend to exceed the MELCCFP resurgence criterion in the core of the pile where the material is stacked the highest, whereas the edge of the pile (lower section of the slopes) remains essentially below the criterion. Moreover, the 2D display is coherent with the results presented in Figure 6, as the leachates arsenic concentration begins to exceed the MELCCFP criterion punctually after about 60 m of percolation (orange dotted line).

The profiles generated for Scenarios II, and III are similar, as no exceedance of the MELCCFP resurgence criterion is observed; although in Scenario II, the maximum arsenic concentrations close to the bottom of the pile remain within the 10 to 20 mg/l range, whereas in Scenario III, they punctually reach the 20 to 30 mg/l range.

Scenario I - Co-deposition

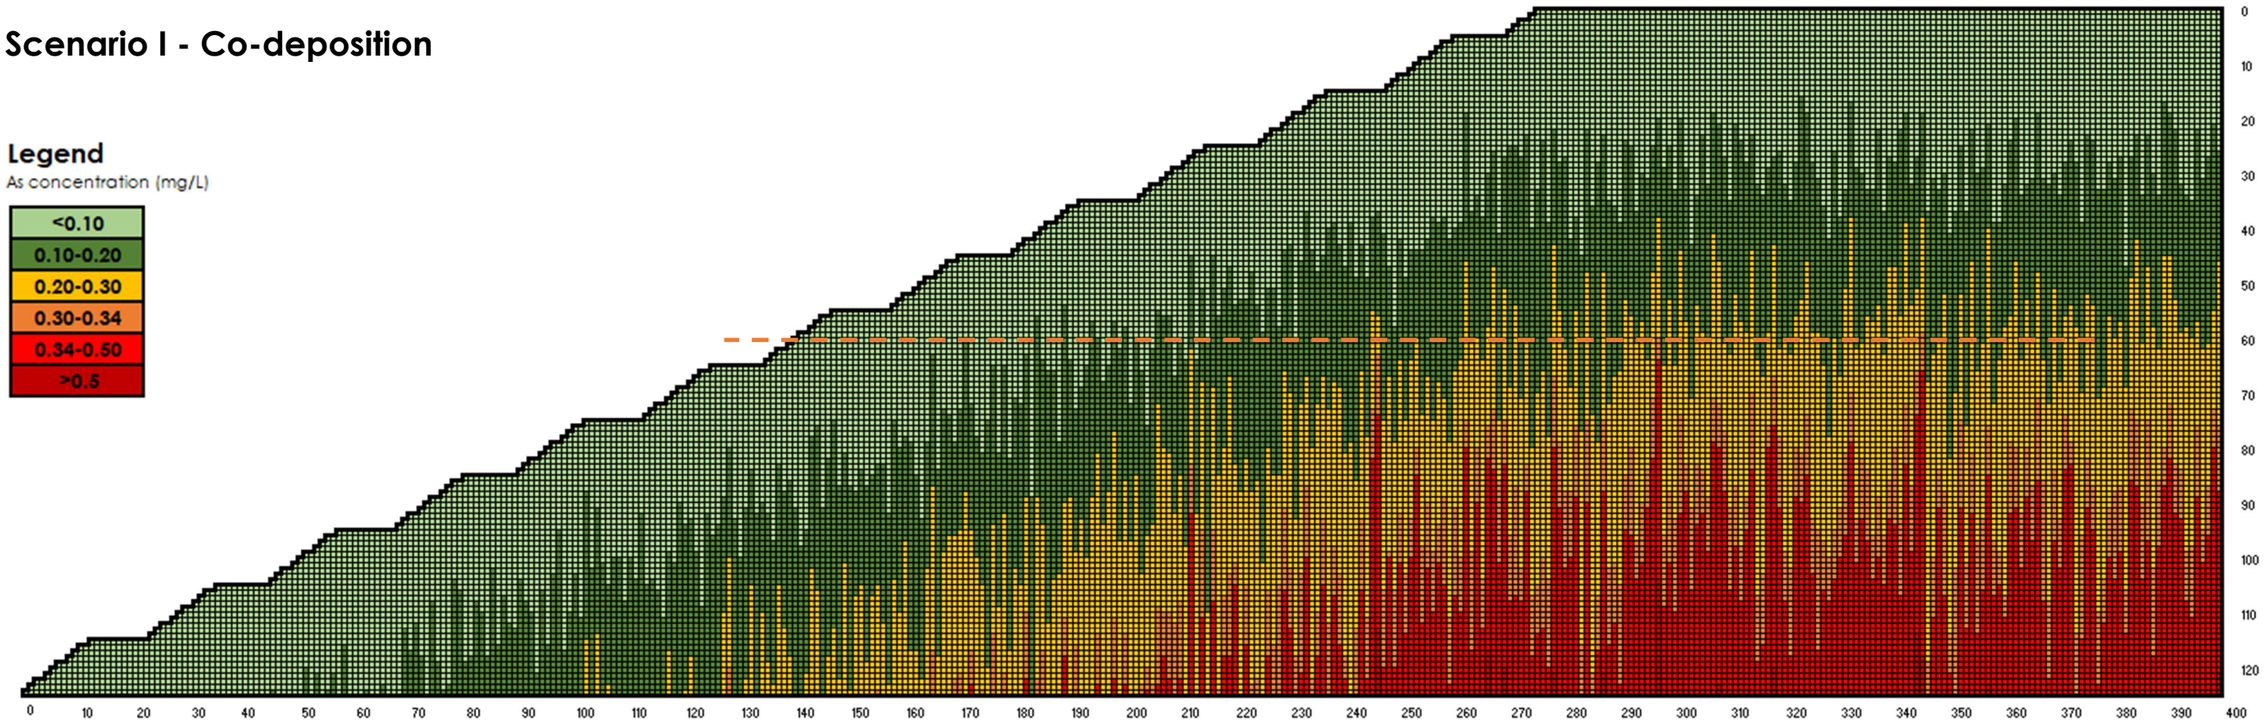

Figure 7: 2D illustration of the arsenic concentration modeling throughout the pile - Scenario I - Co-deposition

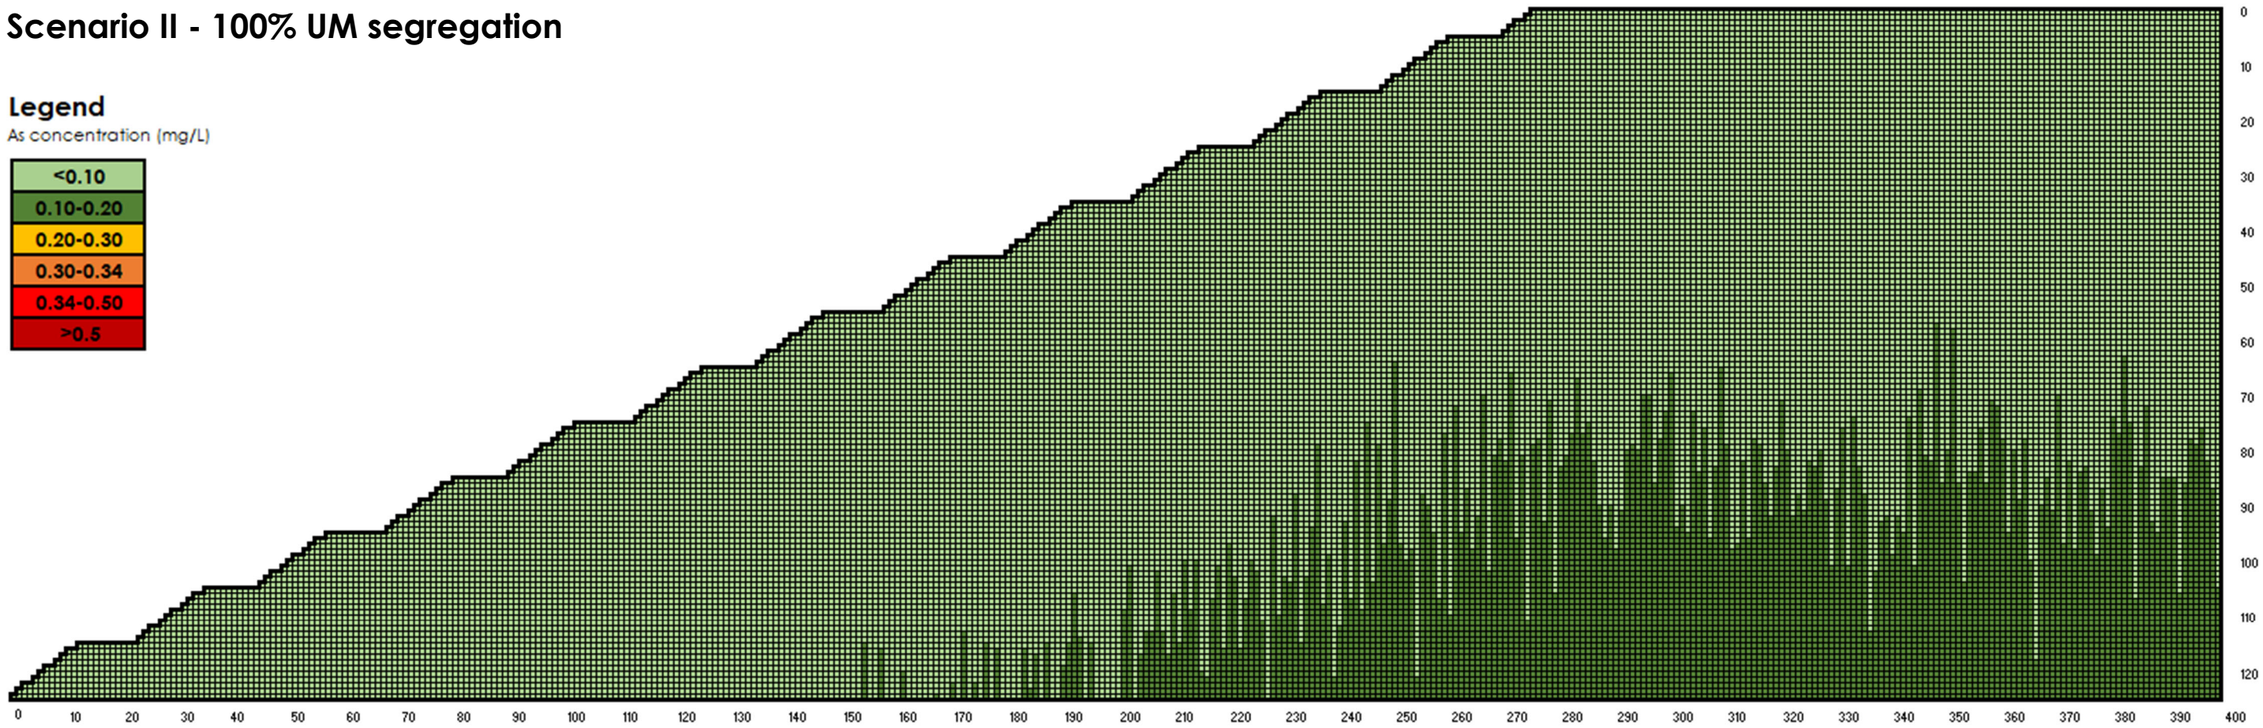

Figure 8: 2D illustration of the arsenic concentration modeling throughout the pile - Scenario II - 100% UM segregation)

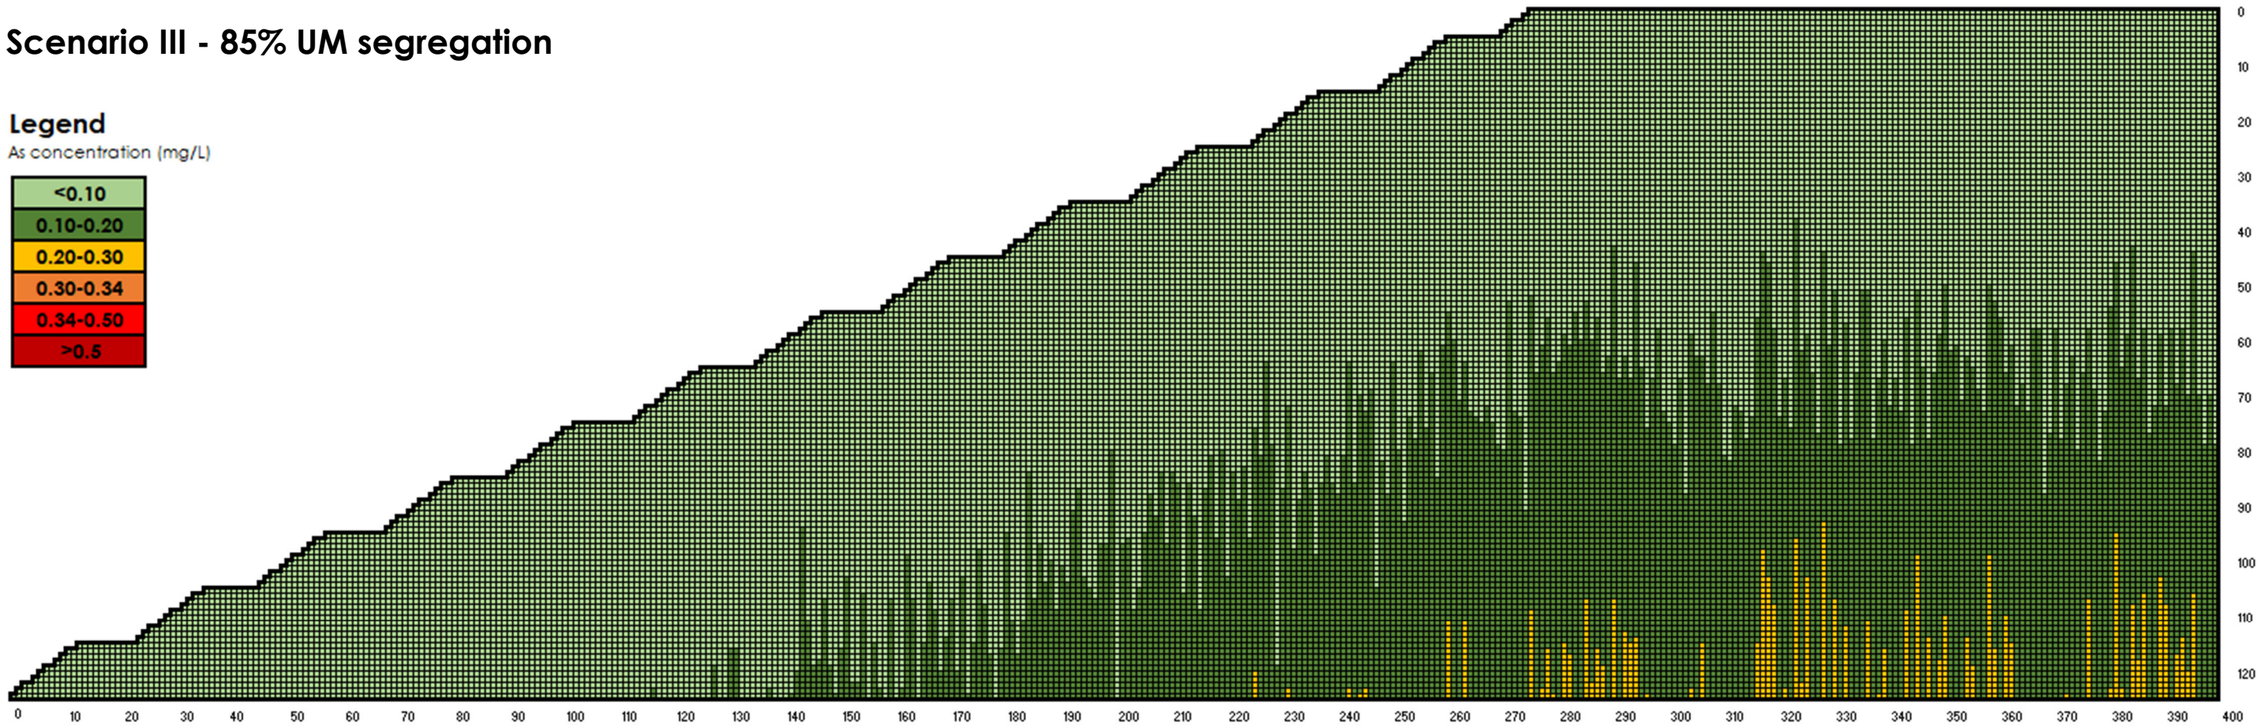

Figure 9: 2D illustration the arsenic concentration modeling throughout the pile - Scenario III - 85% UM segregation

3.3. Sensitivity analysis

The interpretation of modelling results, and the accuracy that can be expected from them should be considered with their sensitivity to the input parameters, and with the degree of confidence one can have of the accuracy of the models input parameters.

The model presented in this study relies on the hypothesis that arsenic mobilization is caused by oxidation as a function of a kinetic rate assumed constant over time. The mobilization rate of arsenic (expressed in mg/kg/week) being constant over time, the arsenic concentration of the water reaching the bottom of the pile and infiltrating the groundwater system is controlled by the water to solid ratio.

It should be mentioned that identification of minerals containing arsenic has not been completed. Therefore, the relative importance of oxidation of sulfide minerals containing arsenic is not known.

The net infiltration rate, therefore, partially controls the arsenic concentration of the leachates. The net infiltration rate used for the model was allowed to fluctuate randomly within the 600 to 800 mm/year range.

Figure 10 shows that the output parameters, namely the pile's bottom arsenic concentration (a), and the pile's elevation cut-off value (b), are proportional to the random infiltration rate of the modeling iteration.

The arsenic concentration at the bottom of the pile decreases as the net infiltration rate increases following a power function, and the cut-off elevation increases as the net infiltration increases following a linear equation. Hence, a variation of the precipitation rate of 1 mm/year will cause a variation of the cut-off elevation of 14 cm, 32 cm, and 41 cm in Scenarios I, II, and III, respectively.

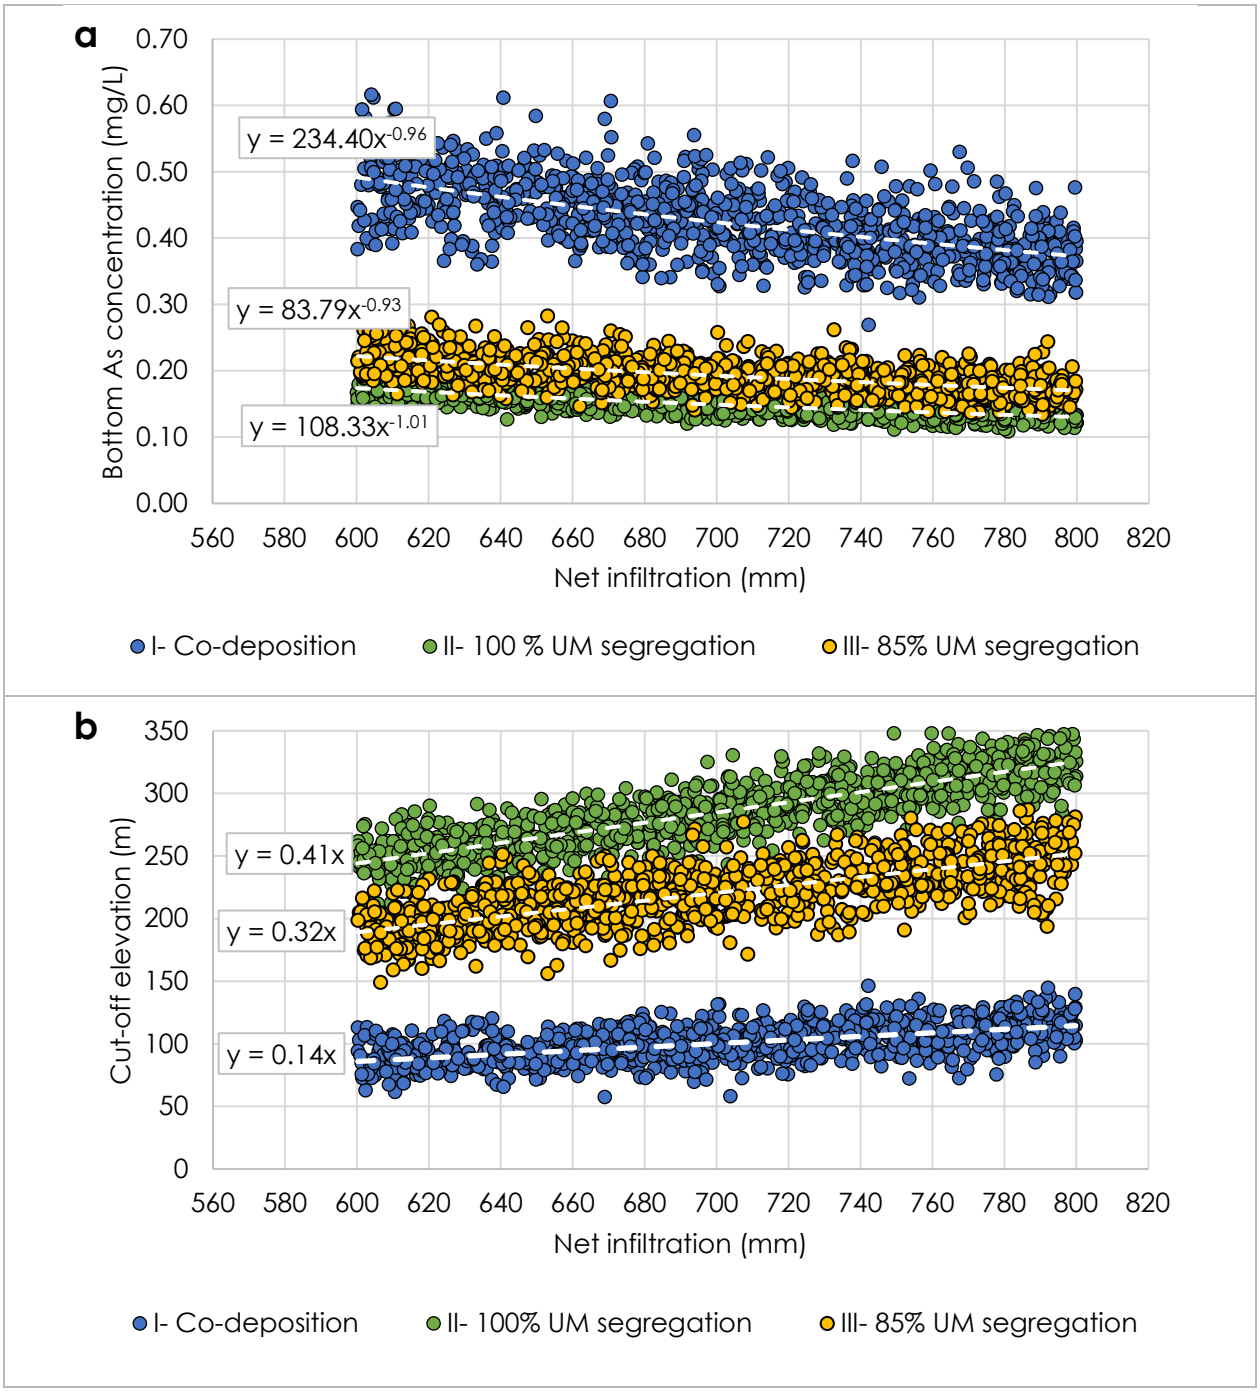

Figure 10: Sensitivity of the arsenic concentrations at the bottom of the pile and cut-off elevation parameters to net infiltration

The results of the analysis are also very sensitive to the variation of the scaling factors used as part of this model, as both of the output parameters (arsenic leachate concentration, and pile cut-off elevation) are directly proportional to their value (Equation 1, Section 2.3). In other terms, the multiplication of a scaling factor by a coefficient of two (2), results in the variation of the output parameter by a factor of two (2) as well.

Moreover, the influence of the scaling factors cumulates, so that the variation of two (2) scaling factors by a coefficient of two (2), or of all three (3) scaling factors by a coefficient of two (2), would result in the variation of the output parameters by a factor of four (4) (= 2^2), and eight (8) (= 23), respectively. The sensitivity of the output parameters to the influence of the scaling factors' variation within a coefficient range of 1 to 10 is illustrated in Figure 11. This observation emphasizes the importance of an appropriate calibration of the scaling factors.

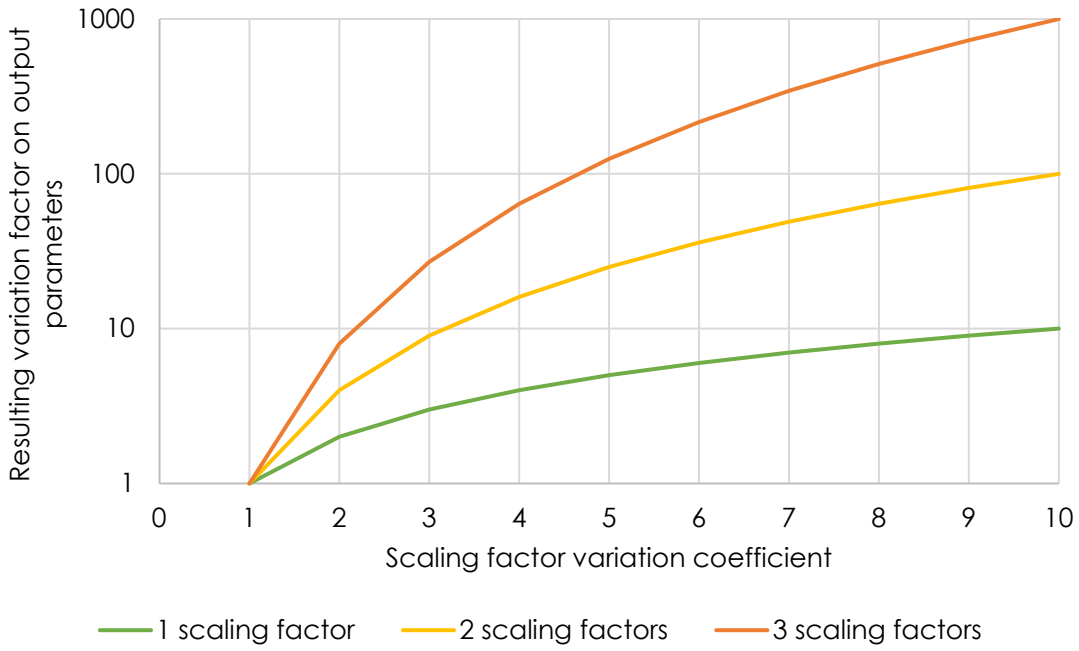

Figure 11: Graphic illustration of the sensitivity of the output parameters to the variation of one, two, or three scaling factors

4. Conclusion

Current projections of the Corvette CV5 Lithium Project entail the displacement and construction of waste rock stockpiles totaling around 700 Mt of mass. The waste rock stockpiles are currently designed to be constructed to 125 m of elevation. However, and hybrid scenario (underground and open-pit mining operations) is being studied and therefore the tonnage of waste rock could be lower and the height of the stockpiles could be reduced.

A geochemical characterization program involving static and kinetic analysis was conducted on selected waste rock samples of the different lithologies identified in the targeted rock body, namely amphibolite, barren pegmatite, metasediment, and ultramafic rock. This program highlighted potential arsenic leaching risks with regard to the MELCCFP resurgence in surface water criterion The ultramafic lithology, in particular, was identified as more prone to arsenic enrichment and, therefore, higher potential leaching risk.

A modeling effort was conducted using static and kinetic test results as well as geochemical data collected from the waste rock material as part of the exploration drilling program. A correlation between HCT arsenic leaching rates and the arsenic contents from the DHDB was determined and utilized to calculate leaching rates for the complete DHDB including 4,968 samples. Scaling factors were then developed to scale these leaching rates to the field conditions and derive source terms for application to the model.

Based on the model hypotheses, the arsenic concentration of the leachates tends to increase progressively as the water percolates further down into the pile; the risk of exceeding the MELCCFP is, therefore, highly dependent on the elevation of the pile of the considered material. Furthermore, it could be determined that in order to prevent arsenic leaching conditions at the bottom of a 125 m pile, an average arsenic content of 40 ppm should not be exceeded.

The analysis of the leaching potential of the separate lithologies revealed that approximately 88% of the amphibolites, 97% of the barren pegmatites, and 92% of the metasediments lie below the average arsenic content of 40 ppm, while approximately 62% of the ultramafic material exceeds this limit. Consequently, it is estimated that arsenic concentrations of percolating waters from an ultramafic pile of approximately 14 m would exceed the MELCCFP resurgence criterion. However, other waste rock lithologies would not result in percolating water concentrations above the guideline when they are stacked up totwice the projected waste rock pile elevation of 125 m.

The different scenarios were tested and ran for 1,000 iterations. Scenario I corresponded to a total co-deposition of all waste rock lithologies in the pile (no segregation); Scenario II corresponded to an ideal case of complete segregation of the ultramafic material, and finally,

Scenario III, which corresponded to a more realistic segregation of 85% of the ultramafic material.

Results showed that the implementation of Scenario I would likely lead to arsenic leaching concentrations that would exceed the MELCCFP resurgence criterion of 0.34 mg/l with estimated concentrations of 0.40 mg/l on average at the bottom of the pile; whereas Scenarios II and III displayed bottom average concentrations of 0.15 and 0.20 mg/l, respectively.

The arsenic concentration exceedances measured for Scenario I translated into pile cut-off elevation values that fell essentially below the projected pile elevation of 125 m, with 101 m on average and a minimum of 58 m; whereas the two other scenarios, on the other hand, presented cut-off elevation values significantly above the 125 m mark with average values of 286 m, and 220 m for Scenarios II and III, respectively.

Based on these results, the main conclusions and recommendations are as follows:

- Approximately 62% of the ultramafic material bears a significant risk of arsenic leaching, and should, therefore, be managed separately and, preferably, mitigation measures such as establishment of a geomembrane liner at the bottom of the pile should be considered. Segregation of ultramafic material showing As leaching potential from ultramafic material showing no as leaching potential is not possible on the field. As said earlier, even complete segregation of ultramafic material from other lithologies is not possible on the filed.
- The other lithologies generally do not pose nearly as much of a risk as the ultramafic material. The most arsenic-rich portions of these lithologies should be diluted enough within the rock mass not to constitute a significant risk.
- The segregation of the ultramafic, even incomplete (Scenario III; 85% segregation), constitutes a promising avenue for the mitigation of arsenic leaching risk that could reduce reliance on costly mitigation measures such as geomembrane liner installation.
- The risks of exceedance of the MELCCFP resurgence criterion are greatest at the basis of the pile's core. Consequently, the possibility of storing the safest material at the centre of the pile and placing the material with intermediate arsenic content on the edges of the pile, where the percolating water path is less significant, should be evaluated.
- The sensitivity analysis showed that the results of the simulations and corresponding conclusions are highly dependant on the correct assessment of the system's water balance as well as scaling factors. Further work should be conducted to evaluate arsenic leaching potential of the material at an intermediate scale, such as barrel tests exposed to field-like climate conditions. This type of test, as well as well as extensive PSD characterization, would help reduce uncertainties on the scaling factors.

- Mineralogical analysis and sequential extraction testing should be carried out in order to understand the geochemistry of arsenic in the various waste rock types, especially the ultramafic lithology.

Déclaration de limites

Ce rapport a été préparé par Vision Geochemistry Ltd. pour PMET Resources Inc. dans le cadre de l'Étude de faisabilité du projet Shaakichiuwaanaan (pegmatite CV5) et fournit une caractérisation géochimique ainsi qu'une modélisation des rejets miniers.

Lors de la préparation de ce rapport, Vision Geochemistry Ltd. s'est appuyé sur des informations provenant de tiers et n'a pas vérifié l'exactitude de celles-ci de manière indépendante. Les résultats, interprétations et conclusions présentés dans ce rapport sont destinés uniquement à une évaluation de niveau faisabilité et ne constituent pas une prédiction définitive des conditions futures. Les interprétations et conclusions relatives à la caractérisation géochimique et à la modélisation des rejets miniers doivent être mises à jour au fur et à mesure de la disponibilité de nouvelles données ou informations.

Bien qu'une attention raisonnable ait été portée à la préparation du rapport, aucune garantie n'est donnée quant à l'exactitude ou l'exhaustivité des données ou des conclusions. Ce rapport doit être utilisé uniquement par PMET Resources Inc. et ses conseillers, en tenant compte et en intégrant pleinement les limites énoncées.

Résumé exécutif

Vision Geochemistry Ltd. (« Vision ») a été mandaté par PMET Resources Inc. (« PMET ») pour réaliser une évaluation géochimique dans le cadre de l'Étude de faisabilité (FS) et de l'Étude d'impact environnemental et social (ESIA) du projet de lithium Shaakichiuwaanaan, situé dans la région administrative du Nord-du-Québec, à environ 345 km à l'est de la baie James. L'objectif principal de cette étude est de caractériser le comportement géochimique des différents matériaux miniers devant être gérés sur le site, d'évaluer les risques environnementaux associés et de soutenir la conception environnementale du site. Au stade de la faisabilité, l'accent a été mis sur l'évaluation des risques liés aux matériaux destinés à être disposés dans les haldes Stockpile-001 (stériles), Stockpile-002 (stériles et résidus) et au parc à minerai.

Un total de 350 échantillons environnementaux, incluant 316 échantillons de stériles provenant de quatre lithologies — amphibolite (n=128), métasédiment (n=101), pegmatite stérile (n=33) et ultramafique (n=54) — ainsi que du minerai (pegmatite à spodumène ; n=25) et des résidus (n=15), ont été soumis à des essais statiques afin d'évaluer leur potentiel de génération d'acide et leur potentiel de lixiviation des métaux.

Les résultats de du bilan acide-base (acid-base accounting, ABA) ont indiqué que 28,2 % des stériles, 88,0 % du minerai (pegmatite à spodumène) et 77,8 % des résidus pouvaient être classés Non-PAG. Globalement, 26,7 % des échantillons de stériles ont été classés PAG, incluant 12,5 % de l'amphibolite (n=16), 35,6 % des métasédiment (n=36), 3,0 % de la pegmatite stérile (n=1) et 5,6 % de l'ultramafique (n=3). En comparaison, le minerai (pegmatite à spodumène) et les résidus ne comptaient que 4,0 % d'échantillons PAG. Tous les échantillons de résidus ont été classés Non-PAG.

Sur la base de l'analyse des données ABA, il a été recommandé d'envisager une ségrégation des matériaux présentant une teneur totale en soufre supérieure à 0,3 % et de les placer dans la halde Stockpile-002 afin de constituer la halde Non-PAG, Stockpile-001.

L'analyse des teneurs extractibles par eau régale a révélé une large gamme d'éléments enrichis par rapport aux concentrations de fond du Province géologique du Supérieur, l'arsenic étant l'élément le plus fréquemment enrichi, avec 79,4 % des échantillons dépassant dix fois la concentration de fond. Les autres éléments enrichis identifiés comprennent le cuivre (40,8 % de dépassements) et le nickel (30,9 % de dépassements).

Les essais de lixiviation SPLP et CTEU-9 ont partiellement reflété les enrichissements observés lors des extractions à l'eau régale, mettant en évidence des éléments similaires. Ces procédures ont permis d'identifier des risques potentiels de lixiviation associés à l'aluminium, l'antimoine, l'arsenic, le cuivre, le nickel, le lithium et l'uranium dans les stériles, le minerai et les résidus. Toutefois, aucun des 350 échantillons testés ne présentait de caractéristiques de « risque élevé » selon la directive 019 (D019).

Les essais cinétiques comprenaient la poursuite de 16 essais en cellules d'humidité (HCT, incluant un doublon) sur les stériles et le minerai, ainsi que le lancement de 5 essais en colonnes sur les résidus. Les données issues des essais cinétiques ont été utilisées pour affiner le criblage des COPC, permettant de confirmer ou d'écarter les risques potentiels de lixiviation. Notamment, les

résultats indiquent que si des conditions acides venaient à se développer dans le Stockpile-002, des métaux de base tels que l'aluminium, le cuivre et le nickel seraient susceptibles d'être lixiviés. De plus, les essais en colonnes sur les résidus ont montré que des dépassements en arsenic, antimoine et, dans une moindre mesure, lithium, pourraient être anticipés dans le Stockpile-002.

Le modèle géochimique des haldes a été élaboré à partir des données cinétiques extrapolées aux conditions de terrain et couplées à une distribution aléatoire des caractéristiques des stériles provenant de la base de données de forage (drillhole database, DHDB ; 4 678 échantillons de stériles). Les modèles visaient à prédire les concentrations en COPC dans les eaux de contact des stériles et des résidus au Stockpile-001 et au Stockpile-002, à soutenir la conception de la halde Stockpile-001 (Non-PAG/Non-ML ; classification D019 – Faible risque), et à éclairer la conception de la halde Stockpile-002 (PAG/ML ; classification D019 – Acidogène/Lessivable) ainsi que du système de traitement des eaux associé.

Les résultats de modélisation indiquent que la mise en place d'un protocole de ségrégation — notamment la séparation de la lithologie ultramafique et de tout matériau présentant une concentration en arsenic supérieure à 30 ppm — devrait prévenir la lixiviation à partir du Stockpile-001, maintenant les concentrations d'arsenic sous le Critère de la Vie Aquatique, Aigu (CVAA) du MELCCFP, ainsi qu'au-dessous des critères du Règlement sur les effluents des mines de métaux et de diamants (MDMER) et de la D019. À l'inverse, des conditions de lixiviation ont été identifiées dans le Stockpile-002, avec des concentrations d'arsenic dépassant les critères MDMER/D019 de jusqu'à deux ordres de grandeur, principalement en raison de la contribution des résidus. De même, l'antimoine et, dans une moindre mesure, le lithium devraient être lixiviés du Stockpile-002, en grande partie en raison des résidus.

Les prédictions de la qualité de l'eau à la halde Stockpile-002 indiquent que l'infiltration des eaux de percolation vers le système d'eau souterraine pourrait se produire si aucune mesure d'atténuation n'est mise en œuvre. Pour prévenir un éventuel retour des contaminants vers les eaux de surface, des mesures de contrôle de l'infiltration seront nécessaires. Par ailleurs, les eaux de drainage provenant de la halde devraient nécessiter une collecte et un traitement avant leur rejet afin de minimiser tout impact environnemental potentiel. Des mesures d'ingénierie et des contrôles opérationnels appropriés seront conçus conformément aux réglementations environnementales applicables et aux meilleures pratiques.

1.0 Introduction

Le projet Shaakichiuwaanaan, mené par PMET Resources Inc. (PMET) et situé dans la région administrative du Nord-du-Québec, à environ 345 km à l'est de la baie James, constitue le plus important projet de développement du lithium en Amérique. Il comprend un gisement principal (CV5) de 77 Mt de pegmatite à spodumène présentant une teneur de 1,44 % Li_2O. Une partie de l'extraction sera réalisée à ciel ouvert, générant un volume substantiel de stériles estimé à 155 Mt, répartis en quatre grands types lithologiques : amphibolites, métasédiment, pegmatites stériles et roches ultramafiques. La gestion adéquate de ces matériaux nécessite de prendre en compte les risques géochimiques liés à la lixiviation de constituants d'intérêt environnemental (constituents of potential concern, COPC), comme l'arsenic en conditions de pH neutre, c'est-à-dire dans le cadre d'un drainage neutre contaminé (neutral rock drainage, NRD), ainsi que la génération de drainage rocheux acide (DRA) résultant de l'oxydation des minéraux sulfurés.

L'objectif principal de cette étude est de caractériser le comportement géochimique des différents matériaux miniers qui seront gérés sur le site, d'évaluer les risques environnementaux associés et de soutenir la conception environnementale du projet. À l'étape de faisabilité, une attention particulière a été portée sur l'évaluation des risques liés aux matériaux destinés à être entreposés dans le Stockpile-001 (stériles), le Stockpile-002 (stériles et résidus), ainsi que dans la halde à minerai.

Ce rapport s'inscrit dans la continuité du programme préliminaire de caractérisation géochimique BBA/Vision (2024a), basé sur un jeu de données limité (n = 84 échantillons). Il intègre également les travaux exploratoires de modélisation réalisés par BBA/Vision (2024b), qui visaient à simuler le comportement géochimique de haldes de stériles présentant diverses géométries et compositions. La présente étude affine ces travaux en fournissant des prédictions géochimiques cinétiques fondées sur la conception ingénierique actuelle et en soutenant les stratégies de gestion de l'eau, des stériles, du minerai et des résidus, ainsi que les estimations correspondantes des coûts en capital (CAPEX), d'exploitation (OPEX) et de restauration.

Le programme de caractérisation géochimique présenté ici a été élaboré pour répondre aux exigences des instances provinciales et fédérales. Plus spécifiquement, l'étude est alignée sur les lignes directrices relatives à la lixiviation des métaux et drainage rocheux acide (ML/DRA) définies dans le Guide de caractérisation des résidus miniers et du minerai (MELCC, 2020), désormais MELCCFP (Ministère de l'Environnement, de la Lutte contre les changements climatiques, de la Faune et des Parcs), tout en tenant compte du Prediction Manual for Drainage Chemistry from Sulphidic Geologic Materials – Report 1.20.1 (MEND, 2009).

2.0 Matériel et méthode

2.1 Conception du programme

La caractérisation géochimique a été menée selon un programme en trois phases. Cette approche séquentielle, itérative et adaptative a été conçue pour permettre d'ajuster chaque phase en fonction des résultats obtenus lors des phases précédentes.

- La phase 1 comprenait la caractérisation géochimique statique des principaux matériaux miniers (stériles, minerai, résidus DMS préliminaires) afin d'établir une première caractérisation, d'identifier les CIE et d'évaluer la variabilité géochimique.
- La phase 2 a été conçue à partir des résultats de la Phase 1, elle portait sur la caractérisation cinétique au moyen d'essais en cellules humides (HCT), afin de mieux comprendre la lixiviation des métaux, la génération de drainage rocheux acide (DRA) et la mobilité des éléments dans le temps. Ces résultats ont servi d'intrants pour les exercices de modélisation géochimique et de qualité de l'eau.
- La phase 3 comprenait la caractérisation statique sur une taille de population d'échantillons conforme aux lignes directrices réglementaires (MELCC, 2020 ; SRK, 1989) (Phase 3a), ainsi que la réalisation d'essais cinétiques d'échelle intermédiaire comprenant colonnes de laboratoire et des essais en barils sur le terrain (Phase 3b).

2.2 Méthodologie d'échantillonnage

La stratégie ayant guidé la sélection des échantillons de stériles miniers et de minerai visait à capturer à la fois la variabilité géochimique et spatiale en ciblant les aspects suivants :

- Un échantillonnage pondéré des unités de stériles en fonction des proportions lithologiques prévues dans le plan d'extraction ;
- La variabilité spatiale le long de la minéralisation ainsi qu'en profondeur ;
- La proximité avec la zone minéralisée ;
- La variabilité géochimique basée sur un premier examen des COPC, notamment l'arsenic, l'antimoine et le lithium ;
- La variabilité des teneurs en sulfures.

Les échantillons ont été sélectionnés dans la base de données DHDB pour constituer des échantillons composites regroupant de 2 à 8 carottes individuelles, représentant idéalement des intervalles continus de 10 m, bien que la longueur réelle des composites varie entre 2 et 12 m selon la disponibilité. Ce niveau de résolution est approprié pour la ségrégation des stériles, car il correspond généralement à la hauteur de banquette d'environ 10 m prévue dans la conception de la future fosse à ciel ouvert. Il contribue également à améliorer la représentativité spatiale en réduisant le poids des intervalles atypiques.

Les échantillons sélectionnés pour les essais statiques des phases 1 et 3 proviennent de rejets d'analyses déjà existants, conservés aux laboratoires SGS de Burnaby (C.-B.). Ces rejets ont été expédiés au laboratoire SGS de Lakefield (ON), où la préparation des échantillons composites a été réalisée. Les échantillons destinés aux essais cinétiques de la phase 2 ont été prélevés dans les archives de carottes, découpés en quarts de carottes, puis expédiés à SGS pour concassage et tamisage à 6,3 mm.

Les échantillons de résidus utilisés dans cette étude ont été fournis par Primero et sélectionnés afin de représenter les principaux flux de traitement attendus du concentrateur. L'approche d'échantillonnage visait à capturer la variabilité géochimique associée aux différents produits de résidus générés au cours du procédé. Des échantillons représentatifs ont ainsi été obtenus pour chacun des flux principaux :

- DMS Flottation ;
- DMS Middlings ;
- Magnétiques (fraction grossière) ;
- Magnétiques (fraction fine) ;
- Résidus de flottation (fraction grossière) ;
- Résidus de flottation (fraction fine) ;
- Bypass fins.

2.3 Inventaire des échantillons

Au total, 316 échantillons de stériles ont été sélectionnés pour les programmes d'essais statiques des phases 1 et 3. Ces échantillons représentaient quatre lithologies généralisées de stériles : amphibolite, métasédiment, pegmatite stérile et roche ultramafique. De plus, 25 échantillons de minerai provenant de la lithologie pegmatite spodumène et 15 échantillons de résidus provenant de divers flux de traitement ont été inclus dans le programme d'essais. Tous les échantillons ont été soumis aux laboratoires SGS pour des essais statiques. De plus, un sous-ensemble de ces échantillons a été soumis à des essais cinétiques.

Le résumé des échantillons par type de matériau, présenté dans le **Tableau 1**, indique que le nombre d'échantillons de stériles collectés représente environ la moitié de la quantité recommandée par les lignes directrices de la SRK (1989). Ce niveau d'échantillonnage est conforme aux pratiques courantes de l'industrie. De plus, la base de données DHDB exhaustive compilée pour ces matériaux dans toute la zone d'extraction pendant la phase d'exploration contribuera à réduire considérablement l'incertitude de l'évaluation.

Tableau 1. Résumé des échantillons prélevés par lithologie et types de matériaux associés

Lithologie	Masse[1] (Mt)	Nombre recommandé d'échantillons[2]	Échantillons de phase 1	Échantillons de phase 3	Total des échantillons
Amphibolite	61	203	30	98	128
Métasédiment	60,5	202	25	76	101
Pegmatite stérile	10,4	84	13	20	33
Ultramafique	23,1	125	6	48	54
Total des stériles	**155,0**	**614**	**74**	**242**	**316**
Minerai (pegmatite spodumène)	77,0	175	8	17	25
Résidus miniers	54,0	123	2	13	15
Total minerai et résidus[3]	**131,0**	**298**	**10**	**30**	**40**

[1]Estimation de l'étude de faisabilité ; [2]SRK (1989) et MELCC (2020) ; [3]Taille de l'échantillon calculée pour le minerai et les résidus combinés, car les deux produits proviennent de la même lithologie.

Le programme de caractérisation géochimique mené sur les échantillons sélectionnés comprenait des méthodes d'essai statiques telles que le bilan acide-base (acid-base accounting ABA) et l'analyse de la teneur en métaux extractibles par digestion partielle à l'eau régale. Il comprenait également des essais de lixiviation statiques, tels que la procédure de lixiviation par précipitation synthétique (SPLP), la CTEU-9 et la procédure de lixiviation caractéristique de la toxicité (TCLP) (**Tableau 2**).

De plus, des essais cinétiques ont été réalisés. Ceux-ci comprenaient des essais en cellules humide (humidity cell test, HCT) effectués sur une sélection d'échantillons énumérés ci-dessus, ainsi que des essais en colonne et des essais sur le terrain (FBT), qui ont été réalisés à partir d'échantillons composites provenant de la sélection et d'échantillons de carottes supplémentaires prélevés dans les archives du projet. Les certificats d'analyse de tous les essais réalisés dans le cadre du présent programme géochimique sont présentés à l'**Annexe A**.

Tableau 2. Résumé des échantillons soumis aux essais statiques

Lithologie	Total des échantillons	ABA	Eau régale	SPLP et CTEU-9	TCLP
Amphibolite	128	128	128	128	41
Métasédiment	101	101	101	101	50
Pegmatite stérile	33	33	33	33	13
Ultramafique	54	54	54	54	8
Total des stériles	**316**	**316**	**316**	**316**	**112**
Minerai (pegmatite spodumène)	25	25	25	25	8
Résidus miniers	9	9	9	9	9

2.4 Bilan acide-base

L'ABA comprend un ensemble de procédures d'essais en laboratoire et un cadre d'interprétation des données conçu pour déterminer si un matériau doit être qualifié de potentiellement générateur d'acide (potentially acid generating, PAG) ou non potentiellement générateur d'acide (non-potentially acid-generating, Non-PAG) en quantifiant et en comparant le potentiel de neutralisation (neutralization potential, NP) et le potentiel d'acidité (acidity potential, AP).

L'ABA a été réalisé conformément à la méthode CEAEQ MA.110 ACISOL1.0, comme recommandé par le Ministère de l'Environnement, de la Lutte contre le Changement Climatique, de la Faune et des Parcs (MELCCFP) dans le *Guide de caractérisation des résidus miniers et du minerai* (2020).

Le NP d'un matériau, exprimé en kg$CaCO_3$/tonne, dépend généralement de la teneur et de la disponibilité en calcite ($CaCO_3$) et en dolomite ($Ca,Mg(CO_3)_2$), car ces minéraux ont tendance à se dissoudre rapidement et à fournir du NP en libérant du CO_3^{2-} lorsqu'ils sont exposés à l'acidité, tout en maintenant un pH neutre dans l'eau de contact. En outre, certains minéraux silicatés peuvent également représenter une partie du NP, bien que leur participation ait tendance à être plus faible en raison de leur vitesse de dissolution plus lente.

La NP d'un matériau peut être mesuré soit directement à l'aide d'une procédure de laboratoire inspirée de la méthode Sobek (Sobek, 1978, appelée ici Sobek-NP), soit théoriquement, sur la base de la teneur en carbone carbonaté (CO_3-NP) de l'échantillon (MEND, 2009).

Le Sobek-NP est estimé en acidifiant un échantillon pulvérisé de matière solide à l'aide d'une solution d'HCl afin d'épuiser tout son potentiel de neutralisation, avant de le titrer à nouveau à un pH de 7 à l'aide d'une solution de Na(OH). La différence entre le HCl et le Na(OH) utilisés pendant l'essai peut être utilisée pour dériver le Sobek-NP du matériau, qui inclut la contribution des minéraux carbonatés et la partie la plus réactive des minéraux silicatés.

Le CO_3-NP est une estimation théorique basée sur l'hypothèse que le NP du matériau repose essentiellement sur la présence de minéraux carbonatés. Le CO_3-NP peut être calculé à partir de la teneur en carbonate ou de la teneur totale en carbone, si la teneur en carbone de l'échantillon s'avère représentative de la teneur en carbonate. L'équation utilisée pour calculer le CO_3-NP est la suivante :

$$CO_3\text{-}NP\ (kgCaCO_3/tonne) = \%C \times (M_{CaCO_3}/M_C) \times 10$$

Où $\%C$ est le pourcentage de carbone carbonaté ou de carbone total, M_{CaCO_3} est la masse molaire du carbonate (= 100,086 g/mol), et M_C est la masse molaire du carbone (= 12,011 g/mol).

Le potentiel d'acidification (PA) des échantillons peut être estimé par un calcul théorique à partir de la teneur en soufre sous forme de sulfure, ou de la teneur totale en soufre, en supposant qu'il est principalement présent sous forme de sulfures similaires à la pyrite. L'équation utilisée pour le calcul du PA est la suivante :

$$AP\ (kgCaCO_3/tonne) = \%S \times (M_{CaCO_3}/M_S) \times 10$$

Où $\%S$ est la teneur en soufre sous forme de sulfure ou la teneur totale en soufre, et M_S la masse molaire du soufre (= 32,065 g/mol).

2.5 Composition chimique globale

Les constituants extractibles (ou environnementalement disponibles) ont été mesurés conformément à la méthode MA du CEAEQ. 200 - Mét. 1.2. Les extraits d'eau régale (digestion partielle) ont été analysés par ICP-MS pour les éléments majeurs, mineurs et traces. Cette méthode d'extraction est conçue pour fournir une estimation des éléments qui peuvent être lessivés sur une longue période par des processus naturels tels que la dissolution et l'oxydation. Les teneurs des extraits d'eau régale ont été comparées aux concentrations moyennes de la croûte continentale.

Il convient de noter que la teneur moyenne de la croûte continentale fait référence à la teneur totale (digestion totale) et que la teneur extractible fait référence à la teneur partielle (digestion partielle). Par conséquent, les comparaisons directes doivent être considérées avec prudence.

Le contenu extractible peut être comparé aux critères A pour les sols présentés dans le « Guide d'intervention – Protection des sols et réhabilitation des terrains contaminés » du MELCCFP (2021).

De plus, des analyses élémentaires totales ont été effectuées sur tous les échantillons de carottes prélevés dans le pit shell via le fusion au peroxyde de sodium. Les données obtenues ont été compilées dans une base de données DHDB comprenant 4 678 échantillons. La DHDB a ensuite été utilisée pour extrapoler les résultats des échantillons environnementaux à l'ensemble de la zone d'extraction.

2.6 Essais de lixiviation

Conformément aux directives du MELCCFP, les échantillons ont été soumis à la méthode CEAEQ MA. 100 – Lix.Com. 1.1. Une partie de l'échantillon sélectionné a été soumise à une série de procédures de lixiviation afin d'évaluer si les matériaux testés sont susceptibles de libérer des COPC dans l'environnement récepteur. Tous les échantillons ont été soumis à la procédure de lixiviation SPLP EPA 1312 (SPLP) et CTEU-9, et une sélection d'échantillons a également été soumise à la procédure TCLP EPA 1311 (TCLP). Les échantillons sélectionnés pour les essais TCLP comprennent 84 échantillons de la phase 1 du programme de caractérisation géochimique, ainsi que les 38 échantillons de stériles classés comme PAG et 7 échantillons de résidus de la phase 3.

Les procédures SPLP, CTEU-9 et TCLP sont conçues pour évaluer la concentration des espèces susceptibles d'être lessivées lorsqu'un matériau est mis en contact avec de l'eau. La méthode SPLP utilise de l'eau acide à un pH de 4,2 afin de simuler des conditions environnementales légèrement acides telles que les pluies acides, tandis que la méthode CTEU-9 utilise simplement de l'eau déionisée et le matériau est broyé à une granulométrie plus fine, exposant ainsi une plus grande surface.

Tous les extraits des essais de lixiviation ont été soumis à une analyse ICP-MS des éléments majeurs, mineurs et traces. De plus, les lixiviats TCLP, SPLP et CTEU-9 ont été analysés pour

déterminer leur teneur en fluorure (F-), sulfate (SO42-), chlorure (Cl-), bromure (Br-), nitrite (NO2-) et nitrate (NO3-) par chromatographie ionique, ainsi que par titrage de l'acidité/alcalinité et par mesure du pH et de la conductivité électrique (CE).

2.7 Critères de classification

2.7.1 Classification par bilan acide-base

Les échantillons dont la teneur totale en soufre est supérieure à 5 % sont de facto qualifiés de PAG, tandis que les échantillons dont la teneur totale en soufre est inférieure à 0,04 % sont classés comme non-PAG. Tous les échantillons intermédiaires sont qualifiés de PAG si le potentiel de neutralisation net (NNP = NP-AP) est inférieur à 20 ou si le rapport de potentiel de neutralisation (NPR = NP/AP) est inférieur à 2. Cependant, les échantillons classés comme PAG sur la base d'essais statiques peuvent être requalifiés comme non-PAG sur la base des résultats d'essais cinétiques. Les critères de sélection pour l'ABA sont résumés dans **Tableau 3**.

Selon MEND (2009), les échantillons présentant un NPR compris entre 1 et 2 peuvent être qualifiés d'incertains en ce qui concerne leur potentiel de génération d'acide et des investigations supplémentaires, telles que des essais cinétiques, peuvent être menées afin d'affiner l'évaluation des risques liés à la génération d'acide.

Tableau 3. Résumé des échantillons soumis à des essais statiques

Paramètres	Valeur	Classification ABA	Procédure
Total S	Moins de 0,04 % en poids de S	Non-PAG	Aucun autre essai
Total S	0,04 % en poids de S	Des essais supplémentaires sont nécessaires.	Essais de prédiction ARD statiques
Total S	>5 % en poids de S	Des essais supplémentaires sont nécessaires.	PAG de facto ; ou essais cinétiques pour valider
NNP	Moins de 20 kg par tonne de CaCO3	PAG	Si l'une des valeurs NNP ou NPR est inférieure à la valeur de classification, l'échantillon est PAG.
NPR	<2	PAG	

2.7.2 Potentiel de lixiviation

Les résultats des essais de lixiviation effectués sur les échantillons sélectionnés ont été évalués conformément aux lignes directrices du MELCCFP.

Afin de mettre en évidence les enrichissements potentiels des matériaux en certains constituants, les résultats des essais de lixiviation à l'eau régale ont été comparés à la

concentration moyenne de la croûte continentale (Rudnick et Gao, 2014) ainsi qu'aux teneurs de fond de la province géologique du Supérieur fournies à l'annexe 1 du Guide d'intervention - protection des sols et réhabilitation des terrains contaminés du MELCCFP.

Les résultats des essais de lixiviation SPLP et CTEU-9 ont été comparés au critère de qualité pour la protection de la vie aquatique – effet aigu (CVAA) du critère de qualité des eaux de surface fourni par le MELCCFP. Les valeurs réglementaires pour certains éléments (par exemple, le cadmium (Cd), le manganèse (Mn)) dépendent de la dureté du réseau hydrographique récepteur, tandis que pour l'aluminium (Al), elles dépendent également de la concentration en carbone organique dissous (dissolved organic carbon, DOC) et du pH. Les valeurs réglementaires ont été calculées en supposant une concentration en DOC de 5 mg/L, un pH de 6 et une dureté de 10 mg/L.

Les résultats du essais de lixiviation TCLP ont été comparés à la directive 019 – Annexe 2 sur les caractéristiques des résidus miniers (à haut risque).

2.8 Essais cinétiques

Différentes approches de essais cinétiques ont été entreprises dans le cadre de ces travaux afin d'étudier la mobilité du COPC au fil du temps. Trois types de essais ont été réalisés, notamment les HCT, les essais en colonne et les FBT, dans le but d'évaluer le comportement géochimique des matériaux dans différentes conditions de taille des particules, de rapport liquide/solide et de température.

Les échantillons d'eau prélevés dans le cadre des essais cinétiques ont été soumis à une série d'analyses, notamment la récupération du volume, le pH et conductivité électrique, titrage de l'acidité/alcalinité, analyse ICP-MS des éléments majeurs, mineurs et traces, ainsi que la caractérisation du fluorure (F^-), du sulfate (SO_4^{2-}), du chlorure (Cl^-), bromure (Br^-), nitrite (NO_2^-) et nitrate (NO_3^-) à l'aide de la chromatographie ionique.

2.8.1 Essais en cellules humides

Les échantillons HCT ont été sélectionnés sur la base des données des essais statiques afin de couvrir tous les types de lithologie et de matériaux, tout en tenant compte de la variabilité des concentrations en arsenic et en soufre documentée dans la DHDB (**Tableau 4**).

La procédure d'essai (ASTM D5744-18) a été réalisée par SGS. Elle consistait à placer 1 kg de matière sèche, broyée à une granulométrie de 6,3 mm, dans une cellule humide, puis à effectuer des cycles hebdomadaires consistant à rincer avec 1 litre d'eau déionisée et à exposer alternativement à de l'air humide et à de l'air sec.

Le rapport liquide/solide de 1 utilisé dans le HCT favorise la lixiviation de tous les composés dissous, permettant ainsi une quantification précise des taux de charge.

Ce rapport présente les résultats des 108 premières semaines du programme HCT, mais les essais devraient se poursuivre jusqu'en octobre 2025.

Le **Tableau 4** présente la liste des quinze HCT (et un doublon), lancés le 27 avril 2023, ainsi que leurs identifiants (ID) correspondants, leurs types lithologiques et leurs caractéristiques en termes d'arsenic et de soufre total.

Table 4. Inventaire des HCT réalisés et lithologie ou types de matériaux correspondants

# HCT	Lithologie
CV5-WR-HCT-2	Amphibolite
CV5-WR-HCT-5	Amphibolite
CV5-WR-HCT-5 (DUP)	Amphibolite
CV5-WR-HCT-14	Amphibolite
CV5-WR-HCT-22	Amphibolite
CV5-WR-HCT-33	Amphibolite
CV5-WR-HCT-36	Ultramafique
CV5-WR-HCT-39	Métasédiment
CV5-WR-HCT-50	Métasédiment
CV5-WR-HCT-56	Métasédiment
CV5-WR-HCT-59	Ultramafique
CV5-WR-HCT-62	Ultramafique
CV5-WR-HCT-64	Pegmatite stérile
CV5-WR-HCT-69	Pegmatite stérile
CV5-WR-HCT-74	Minerai (pegmatite spodumène)
CV5-WR-HCT-76	Minerai (pegmatite spodumène)

2.8.2 Essais en colonne

Cinq essais en colonne (plus un essai en duplicata) utilisant des résidus ont été mis en place le 7 mai 2025 dans le cadre de ce programme de caractérisation géochimique.

Les colonnes de résidus ont été construites de manière à obtenir une couche de 30 cm de matériau, conformément aux directives de l'UQAT (UQAT, 2015), ce qui correspond à environ 8,5 kg de matériau par colonne. En revanche, les colonnes de stériles ont été constituées de 15 kg de matériau. Les colonnes de résidus ont été assemblées à partir de résidus provenant de différents flux de traitement, ainsi que d'un composite maître représentant la composition globale prévue des résidus sortant de l'usine. Les colonnes de stériles ont été construites à partir de diverses lithologies et de matériaux composites correspondants qui devraient être placés dans le Stockpile-001 non lixiviable.

Les six colonnes de résidus sont utilisées comme colonnes de lixiviation, ce qui signifie qu'elles sont rincées toutes les deux semaines en ajoutant 2 L d'eau par le haut. Les colonnes sont ensuite laissées à s'égoutter complètement pendant la nuit par l'orifice inférieur, à partir duquel des échantillons de lixiviat sont prélevés.

Les différents identifiants (#) des essais en colonnes et les configurations expérimentales correspondantes sont résumés dans **Tableau 5**.

Tableau 5. Inventaire des essais sur colonne et configuration expérimentale correspondante

# Essai en colonne	Description des colonnes
CV5-CL-1	Colonne non-saturée installée avec 30 cm de résidus flottants
CV5-CL-2	Colonne non-saturée équipée de 30 cm de résidus moyens
CV5-CL-3	Colonne non-saturée équipée de 30 cm de résidus magnétiques
CV5-CL-4	Colonne non-saturée configurée avec 30 cm de résidus de dérivation
CV5-CL-5	Colonne non-saturée équipée de 30 cm de résidus composites
CV5-CL-6	Colonne non-saturée configurée avec 30 cm de résidus composites

Une modélisation a été réalisée afin de fournir des prévisions des concentrations de COPC dans les eaux d'infiltration et d'exsudation des stériles et des résidus miniers entreposés dans les zones Stockpile-001 et Stockpile-002.

Les modèles géochimiques ont été élaborés à partir des données géochimiques présentées à la section 3.0 ainsi que des données produites dans le cadre d'un programme exhaustif d'analyse de la composition chimique des stériles mené pendant la phase de forage d'exploration du projet. Ce programme visait à créer une base de données géochimiques DHDB afin de faciliter les travaux géométallurgiques et environnementaux futurs. Cette base de données contenant 4 968 analyses d'échantillons de stériles a été utilisée pour soutenir le programme de caractérisation environnementale et les efforts de modélisation présentés dans cette section.

2.9 Modélisation géochimique

La caractérisation géochimique des matériaux présentés dans les sections 3.2 et 3.3 ci-après a permis d'identifier les COPC associés aux matériaux testés (par exemple, l'antimoine, l'arsenic et le lithium), et un effort de modélisation géochimique a été entrepris pour évaluer les risques associés et soutenir une conception technique visant à les atténuer. Plus précisément, la conception du modèle avait trois objectifs principaux qui peuvent être résumés comme suit :

1. Prévision des concentrations d'arsenic dans les eaux de drainage provenant du Stockpile-001 afin d'étayer l'option de séparation des stériles visant à atténuer les risques de lixiviation de l'arsenic associés à la construction du Stockpile-001.
2. Aidez à définir la valeur limite d'arsenic qui permettra de séparer efficacement les matériaux lixiviables des matériaux non lixiviables.
3. Évaluer le potentiel de lixiviation de l'antimoine, de l'arsenic et du lithium des matériaux du Stockpile-002 (roches stériles et résidus miniers) au fil du temps afin d'appuyer la conception technique et le traitement de manière à atténuer efficacement les effets négatifs potentiels sur l'environnement récepteur.

L'approche choisie et développée dans le cadre de l'effort de modélisation peut être résumée selon la séquence en trois étapes suivante :

1. Déterminer l'évolution cinétique des taux de lixiviation du COPC dans les stériles et les résidus miniers et, dans le cas des stériles, établir une corrélation cinétique entre les taux de

lixiviation de l'arsenic mesurés à partir des essais cinétiques et la teneur totale en solides fournie par la DHDB afin d'élaborer des termes sources d'arsenic pour tous les échantillons de la DHDB.

2. Développer et appliquer des facteurs d'échelle pour ajuster les taux de lixiviation calculés à partir des essais cinétiques à l'échelle du terrain.
3. Construire un modèle géochimique temporel simulant la construction progressive des haldes avec, dans le cas des rejets miniers, une distribution aléatoire des lithologies et des teneurs en arsenic, et tester le seuil de coupure de l'arsenic afin d'étudier les taux de lixiviation correspondants.

2.9.1 Modèle conceptuel et hypothèses

Le modèle correspond à une étude préliminaire visant à caractériser le comportement des tas de stériles en matière de lixiviation de l'arsenic. Certaines hypothèses devront être affinées à mesure que la compréhension des caractéristiques physicochimiques du matériau et des conditions sur le terrain progressera avec les développements futurs. La conception du modèle repose sur quatre (4) hypothèses principales :

1. On suppose un état stable. L'effet de la saisonnalité sur le transport réactif géochimique est négligé dans le modèle actuel. Cette hypothèse repose sur le fait que la grande taille du tas et le mouvement relativement lent de l'eau dans la matrice de stériles tendent à compenser l'influence des fluctuations climatiques telles que l'alternance des périodes humides et sèches et les variations interannuelles. De plus, on suppose que les vitesses de réaction sont réparties uniformément dans tout le tas et restent stables tout au long de l'année. Cette hypothèse est étayée par le fait que l'épaisseur des roches stériles formant le tas atténue les variations saisonnières de température à moins de ±1 °C au-delà de 5 m dans le tas.
2. Toutes les précipitations – 591 mm/an, selon le modèle climatique fourni par AtkinsRéalis (AtkinsRéalis, 2025) – sont supposées s'infiltrer dans le tas, et l'évaporation est considérée comme négligeable. Ces hypothèses sont étayées par le fait que des ouvrages d'art seront construits pour limiter les ruissellements, et que la conductivité hydraulique élevée du matériau favorisera une infiltration rapide et une remontée capillaire minimale.
3. Les propriétés physiques telles que la distribution granulométrique, la température et la conductivité hydraulique sont considérées comme homogènes dans l'ensemble du tas, et les lithologies et les taux de lixiviation de l'arsenic associés sont répartis de manière aléatoire dans le modèle. En plus d'être une hypothèse simplificatrice, la répartition aléatoire des propriétés géochimiques permet une analyse statistique de l'influence de l'emplacement des matériaux de stériles de différentes lithologies à l'intérieur du tas sur la concentration des lixiviats d'arsenic.
4. Le modèle ne prend en compte que le transport vertical 1D et ignore les flux latéraux. Cette hypothèse simplifie la modélisation et est étayée par le fait que la conductivité hydraulique des stériles est relativement élevée, ce qui permet au matériau de se drainer rapidement.

2.9.2 *Développement des termes sources*

Les données cinétiques présentées dans la **Section 3.3** du présent rapport ont été utilisées pour élaborer les termes sources cinétiques pour les stériles et les résidus miniers.

Des équations exponentielles de Weibull ont été utilisées pour ajuster les résultats des essais cinétiques et calculer l'évolution des termes sources des COPC au fil du temps.

Où $R_{(t)}$ est le taux de lixiviation à un moment donné t après le début de l'altération du matériau, k est la constante de vitesse et n est un paramètre de forme contrôlant la courbure de la fonction.

Le modèle de type Monte Carlo a été développé uniquement pour le modèle de stériles et a été appliqué spécifiquement à l'arsenic, qui s'est révélé être le COPC le plus problématique identifié dans ce projet en raison de sa forte lixiviabilité à pH neutre. Le modèle de type Monte Carlo a été conçu pour simuler le placement de types de matériaux de lithologie différente et de teneur totale en arsenic différente.

Une équation exponentielle de type Weibull a été utilisée pour calculer l'évolution du rapport entre le taux de lixiviation de l'arsenic HCT et la teneur en arsenic (totale) obtenue par fusion au peroxyde de sodium à partir du DHDB. Ce rapport, appelé ici paramètre cinétique $K_{(t)}$ et exprimé en semaine^{-1} diminue au fil du temps à mesure que les rejets miniers s'altèrent, suivant la tendance décrite dans l'**Équation 1** :

$$K_{(t)} = K_0 \exp\left(-|k \cdot t|^n\right) \qquad \textbf{Équation 1}$$

Dans lequel K_0 est la valeur du facteur cinétique à $t = 0$, k est la constante de vitesse et n est un paramètre de forme contrôlant la courbure de la fonction. Les paramètres k et n être ajusté manuellement jusqu'à ce que l'ajustement approprié de la mesure expérimentale soit obtenu.

Le graphique présenté dans la **Figure 1** illustre l'équation de Weibull utilisée pour ajuster la décroissance mesurée du rapport entre le taux de lixiviation HCT et la teneur totale en arsenic des stériles.

Le taux de lixiviation de l'arsenic $R_{(t)}$ (mg/kg/semaine) est ensuite calculé pour une période t (semaine) en utilisant le paramètre cinétique (semaine^{-1}) une teneur totale initiale en arsenic C_0 comme décrit dans l'**Équation 2** :

$$R_{(t)} = C_0 \times K_{(t)} \qquad \textbf{Équation 2}$$

Les équations exponentielles de Weibull ont également été utilisées pour ajuster les résultats des essais cinétiques sur les colonnes de résidus et pour calculer l'évolution des termes sources COPC (c'est-à-dire l'antimoine, l'arsenic et le lithium) au fil du temps. Comme un seul type de matériau a été simulé, l'**Équation 3** a été directement appliquée aux tendances de charge en COPC pour calculer le taux de lixiviation $R_{(t)}$ au fil du temps t.

$$R_{(t)} = R_0 \exp\left(-|k \cdot t|^n\right)$$ **Équation 3**

Tableau 6 résume les constantes de vitesse (k) et les paramètres de forme (n) utilisés pour ajuster les courbes du modèle aux données expérimentales, avec les ajustements obtenus pour les charges d'arsenic (**a**), d'antimoine (**b**) et de lithium (**c**) indiqués dans la **Figure 2**.

Tableau 6. Résumé des valeurs des paramètres d'ajustement des courbes de modélisation

Type de matériau	COPC	K_0/C_0[1]	k	n
Roche stérile	Arsenic	$1{,}2\times10^{-2}$	0,08	0,40
Résidus miniers	Arsenic	0,53	0,15	0,35
	Antimoine	0,16	0,30	0,30
	Lithium	0,16	0,25	0,40

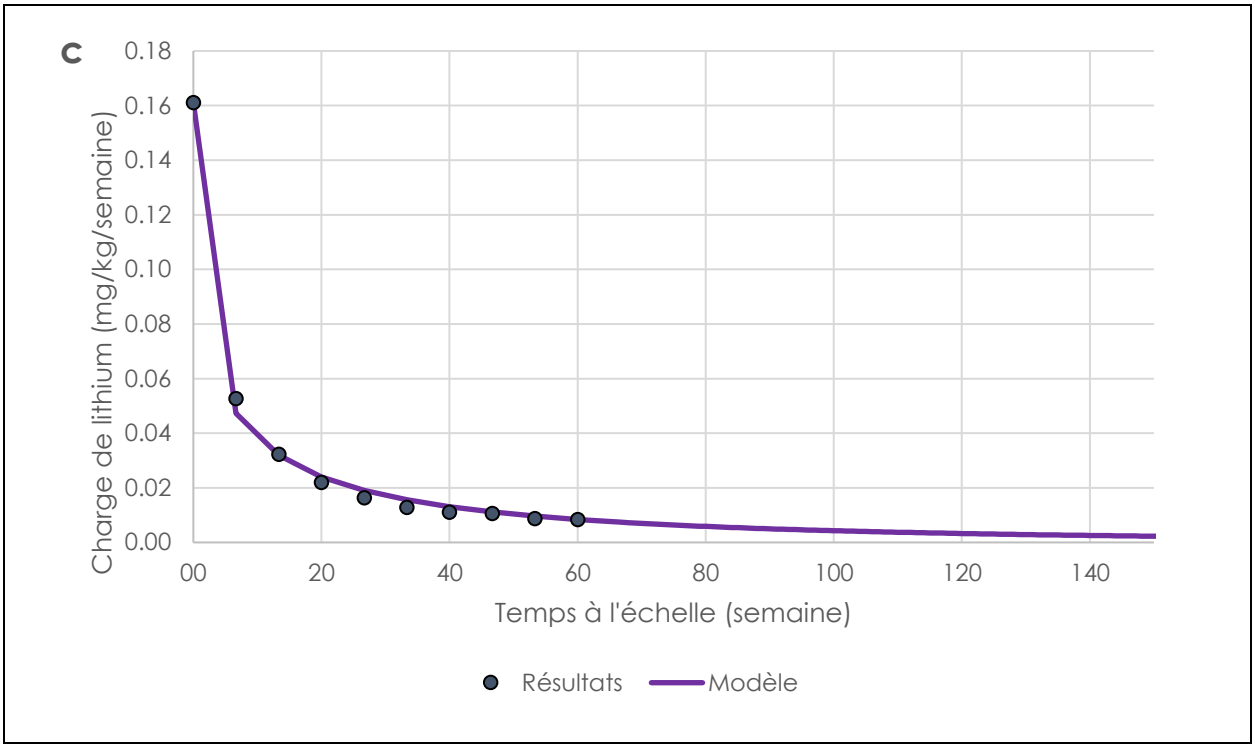

Figure 2. Diminution du taux de lixiviation des résidus miniers COPC au fil du temps (2 de 2)

2.9.3 Facteurs d'échelle

Les conditions d'essai dans lesquelles les taux de lixiviation HCT sont mesurés en laboratoire ne sont pas représentatives du terrain. Trois (3) phénomènes principaux sont généralement reconnus comme expliquant les écarts entre le comportement géochimique dans une halde à stériles et les HCT. Il s'agit de la distribution granulométrique (particle size distribution, PSD), de la température et de l'isolation hydraulique. Des facteurs d'échelle sont généralement utilisés pour ajuster le taux de lixiviation mesuré en laboratoire et dériver des termes sources qui seront plus représentatifs des conditions sur le terrain.

Pour le modèle utilisé dans cette étude, le taux de lixiviation des tas de stériles a été calculé à l'aide de l'**équation 4** suivante. (Kempton, 2012):

$$R_{WRP} = R_{HCT} \times S_{PSD} \times S_{Temp.} \times S_{Salut}$$ **Équation 4**

Tel que :

R_{WRP} est le taux de lixiviation dans le tas de stériles (mg/kg/semaine)

R_{HCT} est le taux de lixiviation dans le HCT (mg/kg/semaine)

S_{PSD} est le facteur d'échelle PSD (sans unité)

$S_{Temp.}$ est le facteur d'échelle de température (sans unité)

S_{Salut} est le facteur d'échelle d'isolation hydraulique (sans unité)

2.9.3.1 *Granulométrie des matériaux*

Sur un site minier, la distribution granulométrique des stériles varie généralement entre l'échelle micrométrique et l'échelle métrique. Cependant, à des fins de normalisation et pour des raisons pratiques, ces matériaux doivent être tamisés avant d'être testés en laboratoire. Les particules plus petites ayant un rapport surface/volume plus élevé que les particules plus grosses, la lixiviabilité dépend fortement de la surface spécifique. Par conséquent, afin de garantir la représentativité, le taux de chargement des stériles dans les conditions de laboratoire doit être adapté pour refléter les conditions sur le terrain. Dans les essais en cellule humide (HCT), les particules sont généralement tamisées et/ou broyées jusqu'à un diamètre maximal de 6,4 mm.

Une analyse documentaire menée par Stockwell et al. (2006) a conclu que plus de 80 % de l'altération géochimique provient de particules de moins de 25 mm, une fraction qui ne représente elle-même que 10–40 % du total des stériles, selon les méthodes de dynamitage et le type de roche. La fraction inférieure à 6,4 mm en représente une part encore plus faible. De plus, les roches ignées et les sédiments fortement métamorphisés—tels que ceux que l'on trouve dans le projet Corvette Lithium—sont connus pour générer moins de fines lorsqu'ils sont dynamités (Dawson, 1994). Par exemple, le projet Goliath, où les stériles sont principalement composés de granit, de métasédiments et de schistes, rapporte qu'environ 5 % des particules sont inférieures à 2,5 mm (Ecometrix, 2014).

L'équipe d'ingénieurs miniers de G Mining Services Inc., chargée de la conception des opérations, y compris le dynamitage, a fourni à Vision la courbe caractéristique de la taille des particules attendue (G Mining, 2025) pour les différentes lithologies extraites sur le site (**Figure 3**).

En supposant une sphéricité homogène et une densité spécifique constante pour toute la distribution granulométrique, il est possible d'estimer le rapport surface/volume des matériaux en fonction de leur granulométrie. En comparant le rapport surface/volume des stériles in situ prévus avec celui du matériau HCT à l'échelle du laboratoire, on peut dériver un facteur d'échelle granulométrique. En suivant cette approche, un facteur d'échelle de 0,05 a été appliqué dans le cadre de la modélisation.

Étant donné que la distribution granulométrique des résidus soumis à des essais en colonne n'a pas été modifiée et qu'elle est représentative du matériau qui sera placé dans le Stockpile-002, aucun facteur d'échelle granulométrique n'a été appliqué dans le cadre de la modélisation des résidus.

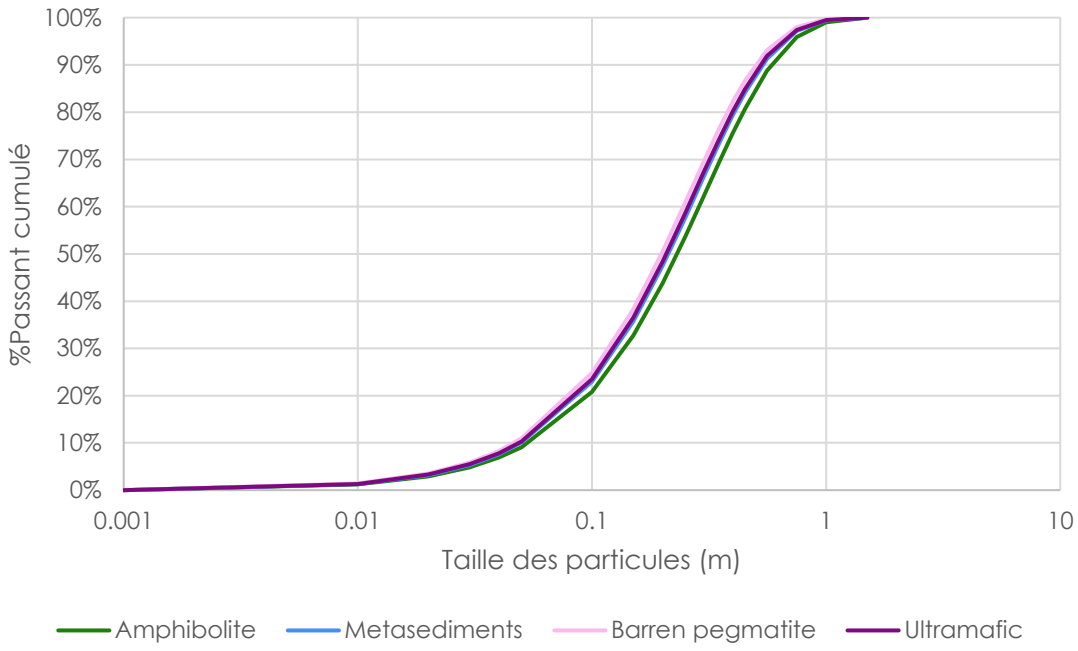

Figure 3. Granulométrie anticipée des stériles

2.9.3.2 *Température*

L'analyse minéralogique effectuée sur des échantillons de stériles a montré que l'arsenic est associé à des minéraux contenant de l'arsénopyrite, tels que la nickeline, la gersdorffite et l'arsénopyrite. La lixiviation de l'arsenic à partir de ces minéraux peut se produire par divers processus dépendants de la température, notamment l'altération oxydative et la dissolution minérale. Ainsi, les vitesses de réaction devraient varier en fonction de la température et peuvent être décrites à l'aide de la loi d'Arrhenius. L'**équation 5**, dérivée de la loi d'Arrhenius, a été utilisée pour déterminer le facteur d'échelle de température pour les vitesses de lixiviation modélisées :

$$SF_{Temp} = \mathrm{Exp}\left(\frac{E_a(T_{terrain} - T_{Laboratoire})}{RT_{Terrain}T_{Laboratoire}}\right)$$ **Équation 5**

Telle que :

- E_a est l'énergie d'activation de la réaction d'oxydation de la pyrite susceptible d'être responsable de la libération des métaux (42 kJ/mol ; (Nicholson, et al. 1988))
- $T_{Terrain}$ et $T_{Laboratoire}$ sont respectivement la température moyenne sur le terrain et en laboratoire (K)
- R est la constante universelle des gaz (8,314 J/mol/K)

L'énergie d'activation apparente de 40 kJ/mol qui a été utilisée dans le modèle cinétique pour décrire la dépendance à la température de la libération d'arsenic à partir de minéraux contenant de l'arsenic, en particulier l'arsénopyrite (FeAsS), la nickeline (NiAs) et la gersdorffite (NiAsS). Cette valeur se situe dans la partie inférieure de la fourchette généralement rapportée pour la mobilisation de l'arsenic dans des conditions acides à quasi neutres (Neil et al. 2015).

Une température moyenne de l'air de -2 °C a été appliquée sur la base de méthodes de télédétection (Wang et al., 2013) reflétant les conditions du site. Cette valeur a été ajustée de manière conservatrice à 2 °C afin de tenir compte de la différence naturelle entre les températures de l'air et du sol, et une température de 22,5 °C a été utilisée pour les vitesses de réaction HCT en laboratoire. Ces valeurs ont donné lieu à un facteur d'échelle de température de 0,30. Cette valeur est corroborée par MEND (2006). Elle a été appliquée à la modélisation des stériles et des résidus miniers.

2.9.3.3 *Isolation hydraulique*

Le facteur d'isolation hydraulique est lié à la structure interne des haldes, qui présentent une grande variabilité en termes de conductivité hydraulique non saturée. Le facteur de contact explique une réduction de la lixiviation, car certaines parties des piles devraient devenir hydrauliquement isolées en raison du développement de voies d'écoulement préférentielles, ce qui se traduit par un rinçage partiel ou moins fréquent par l'eau interstitielle par rapport aux conditions HCT.

Ce facteur est influencé par la faible proportion de particules fines, car l'eau dans les milieux hétérogènes a tendance à s'écouler préférentiellement à travers les zones à grains plus fins. Compte tenu de la rareté prévue des fines dans les stériles de ce projet, l'isolation hydraulique de nombreux amas de matériaux est probable.

Une analyse documentaire des études de modélisation géochimique a permis d'identifier un large éventail de facteurs d'isolation hydraulique, allant de 0,03 à 0,77, les valeurs les plus couramment rapportées se situant entre 0,05 et 0,20 (Rescan, 2013 ; Lorax, 2014 ; Stantec, 2017).

En raison de la faible proportion prévue de fines dans les stériles et du risque associé de formation de grappes isolées de fines, une valeur de 0,10 a été choisie pour cette étude de modélisation.

Étant donné que les résidus miniers sont de taille plus homogène, un facteur d'échelle hydraulique de 0,30 a été appliqué à la modélisation géochimique du tas de résidus Stockpile-002.

2.9.4 *Autres mécanismes à l'échelle du terrain influençant la mobilisation de l'arsenic*

Au-delà de la température, de la taille des grains et de l'isolation hydraulique, plusieurs mécanismes géochimiques peuvent exercer un contrôle sur la mobilisation de l'arsenic dans des conditions réelles. L'un des processus clés est la reprécipitation de l'arsenic dans des phases minérales secondaires, telles que les arsénates de fer (par exemple, la scorodite), ou son incorporation dans des oxyhydroxydes de fer nouvellement précipités, qui peuvent réduire considérablement les concentrations d'arsenic dissous. De plus, la sorption de l'arsenic sur les minéraux ferreux (par exemple la ferrihydrite, la goethite, l'hématite et la magnétite) joue un rôle

essentiel dans l'atténuation de l'arsenic ; ces minéraux forment des complexes solides avec l'As(III) et l'As(V), immobilisant efficacement l'arsenic dans de nombreuses conditions environnementales.

Il est important de noter que le rapport liquide/solide de 1:1 (1 l/kg/semaine) du HCT qui a servi de base à cette évaluation est généralement supérieur de plusieurs ordres de grandeur à celui observé dans les conditions réelles, où les rapports sont généralement de l'ordre de 10^{-3}l/kg/semaine. Ce rapport artificiellement élevé est conçu pour évaluer le taux maximal d'altération des minéraux primaires contenant de l'arsenic et conduit à des estimations très conservatrices des taux de charge en arsenic, car les mécanismes contrôlés par la solubilité (par exemple, la précipitation secondaire ou la libération limitée par sorption) sont submergés. À ce stade des travaux de modélisation, ces mécanismes n'ont pas encore été pris en compte et l'approche reste conservatrice à cet égard. L'affinement de l'évaluation de l'impact environnemental et social (EIES) intégrera les résultats des essais en colonne et sur le terrain, qui utilisent des rapports liquide/solide plus réalistes, permettant une modélisation explicite de la formation de la phase secondaire et des processus de sorption afin de mieux limiter les prévisions de libération d'arsenic.

2.9.5 Conception technique

Un protocole de séparation a été élaboré afin de séparer les stériles PAG/ML des stériles non PAG/non ML dans le but de concevoir une halde à stériles non PAG/non ML (classification D019 : faible risque).

Comme déterminé précédemment, la lithologie ultramafique a été identifiée comme étant plus susceptible de présenter une teneur en arsenic plus élevée associée à une lixiviation de l'arsenic, et une corrélation entre la teneur en arsenic et le taux de lixiviation de l'arsenic a pu être établie. En outre, l'analyse ABA a permis d'identifier une valeur seuil pour la teneur totale en soufre à partir de laquelle les matériaux peuvent être classés comme non PAG, à condition que la concentration totale en soufre soit inférieure à la valeur seuil. Sur la base de ces observations, un processus de modélisation itératif a été engagé entre les équipes d'ingénierie de Vision, Atkins et G Mining afin de proposer une conception répondant à la fois aux réglementations environnementales et à la faisabilité économique. Ce processus itératif a finalement conduit à l'élaboration d'un protocole de ségrégation visant à réduire la dépendance à l'égard de mesures telles que la mise en place d'une membrane géomembrane à grande échelle pour toutes les haldes à stériles.

2.9.5.1 Approche de ségrégation et efficacité

Tous les matériaux ultramafiques feront l'objet d'une séparation. Cependant, une efficacité de séparation conservatrice de 94 % a été supposée pour la lithologie ultramafique, sur la base des informations fournies par G Mining, la société responsable du modèle géologique en blocs. Cette valeur reflète la précision spatiale avec laquelle cette lithologie peut être délimitée dans la zone d'excavation modélisée. Dans le modèle de blocs, les matériaux ultramafiques sont enfermés dans une enveloppe géologique distincte qui capture environ 94 % de leur volume total. En raison de sa continuité, de ses limites bien définies et de ses caractéristiques visuelles distinctives, la lithologie ultramafique se prête à une identification visuelle et à une manipulation

sélective sur le terrain. Ces attributs confirment la faisabilité d'une séparation opérationnelle pendant l'excavation et le placement, permettant ainsi d'exclure la plupart des matériaux ultramafiques des haldes non lixiviables. Les 6 % restants sont supposés représenter soit des matériaux mal classés, soit un mélange aux marges lithologiques, et sont explicitement pris en compte dans le modèle.

En plus de la séparation des matériaux ultramafiques, il a été recommandé de mettre en œuvre un traitement sélectif basé sur une concentration limite d'arsenic de 30 ppm. Des travaux supplémentaires sont nécessaires pour affiner la manutention sélective, mais la séparation peut être effectuée pendant le processus de dynamitage en mesurant les concentrations d'arsenic à l'aide d'un analyseur portable à fluorescence X (pXRF) sur les déblais de forage générés pendant le forage des trous de mine. Cette méthode permet un criblage géochimique en temps réel de la roche dans la fosse avant l'excavation. Sur la base de la distribution spatiale prévue de l'arsenic dans le gisement et de la résolution offerte par l'échantillonnage des trous de mine, cette approche devrait permettre d'exclure environ 90 % des matériaux dépassant le seuil de 30 ppm. Un taux d'erreur de classification d'environ 10 % est supposé, en raison de l'hétérogénéité inhérente à la roche et des limites de la représentativité des échantillons à l'échelle du dynamitage. Cette incertitude sera intégrée dans le modèle et évaluée plus en détail grâce à une validation continue pendant les opérations.

Enfin, il est recommandé de mesurer la teneur totale en soufre des déblais de forage générés lors du forage de trous de mine à l'aide d'une analyse par combustion LECO, une méthode de pyrolyse à haute température. Sur la base de cette analyse, les stériles dont la teneur totale en soufre dépasse 0,30 % doivent être séparés afin d'éviter l'inclusion de matériaux PAG dans le haldes non lixiviable. Ce seuil a été sélectionné sur la base de l'analyse ABA.

2.9.5.2 Conceptions de haldes

Au-delà de la température, de la taille des grains et de l'isolation hydraulique, plusieurs mécanismes géochimiques peuvent exercer un contrôle sur la mobilisation de l'arsenic.

Deux stockages ont été conçus par Atkins (AtkinsRéalis, 2025) sur la base de la stratégie proposée pour la gestion des stériles, des données provenant de la DHDB, du plan d'extraction pour la durée de vie de la mine (life of mine, LOM) et des contraintes liées à la superficie du site. Le premier, appelé Stockpile-001, accueillera les matériaux classés comme non lixiviables, tandis que le second, appelé Stockpile-002, recevra les matériaux classés comme lixiviables. En outre, le Stockpile-002 sera utilisé pour accumuler environ 54 Mt de résidus qui seront déposés sous forme de piles sèches à la périphérie du tas. Une fois le Stockpile-001 terminé, les matériaux non lixiviables restants seront envoyés au Stockpile-002 jusqu'à ce que le tas soit complet.

La **Figure 4** présente la fréquence cumulative des teneurs en arsenic (**a**) et en soufre total (**b**).

a. Le premier graphique confirme la prédominance des matériaux ultramafiques dont la teneur en arsenic est supérieure à 30 ppm (76 %), tandis que l'amphibolite, les métasédiments et la pegmatite stérile présentent 20 % ou moins de matériaux dont la teneur en arsenic est de 30 ppm.

b. Le deuxième graphique montre que les métasédiments présentent la plus forte proportion d'échantillons dépassant le seuil de 0,30 % de soufre total (29 %), suivis par les amphibolites et les matériaux ultramafiques avec respectivement 14 % et 11 %, et enfin la pegmatite stérile, qui présente moins de 0,2 % de matériaux dépassant le seuil de 0,30 %.

La proportion des dépassements des seuils d'arsenic et de soufre total par lithologie est résumée dans le **Tableau 7** et la composition des haldes est présentée dans le **Tableau 8**.

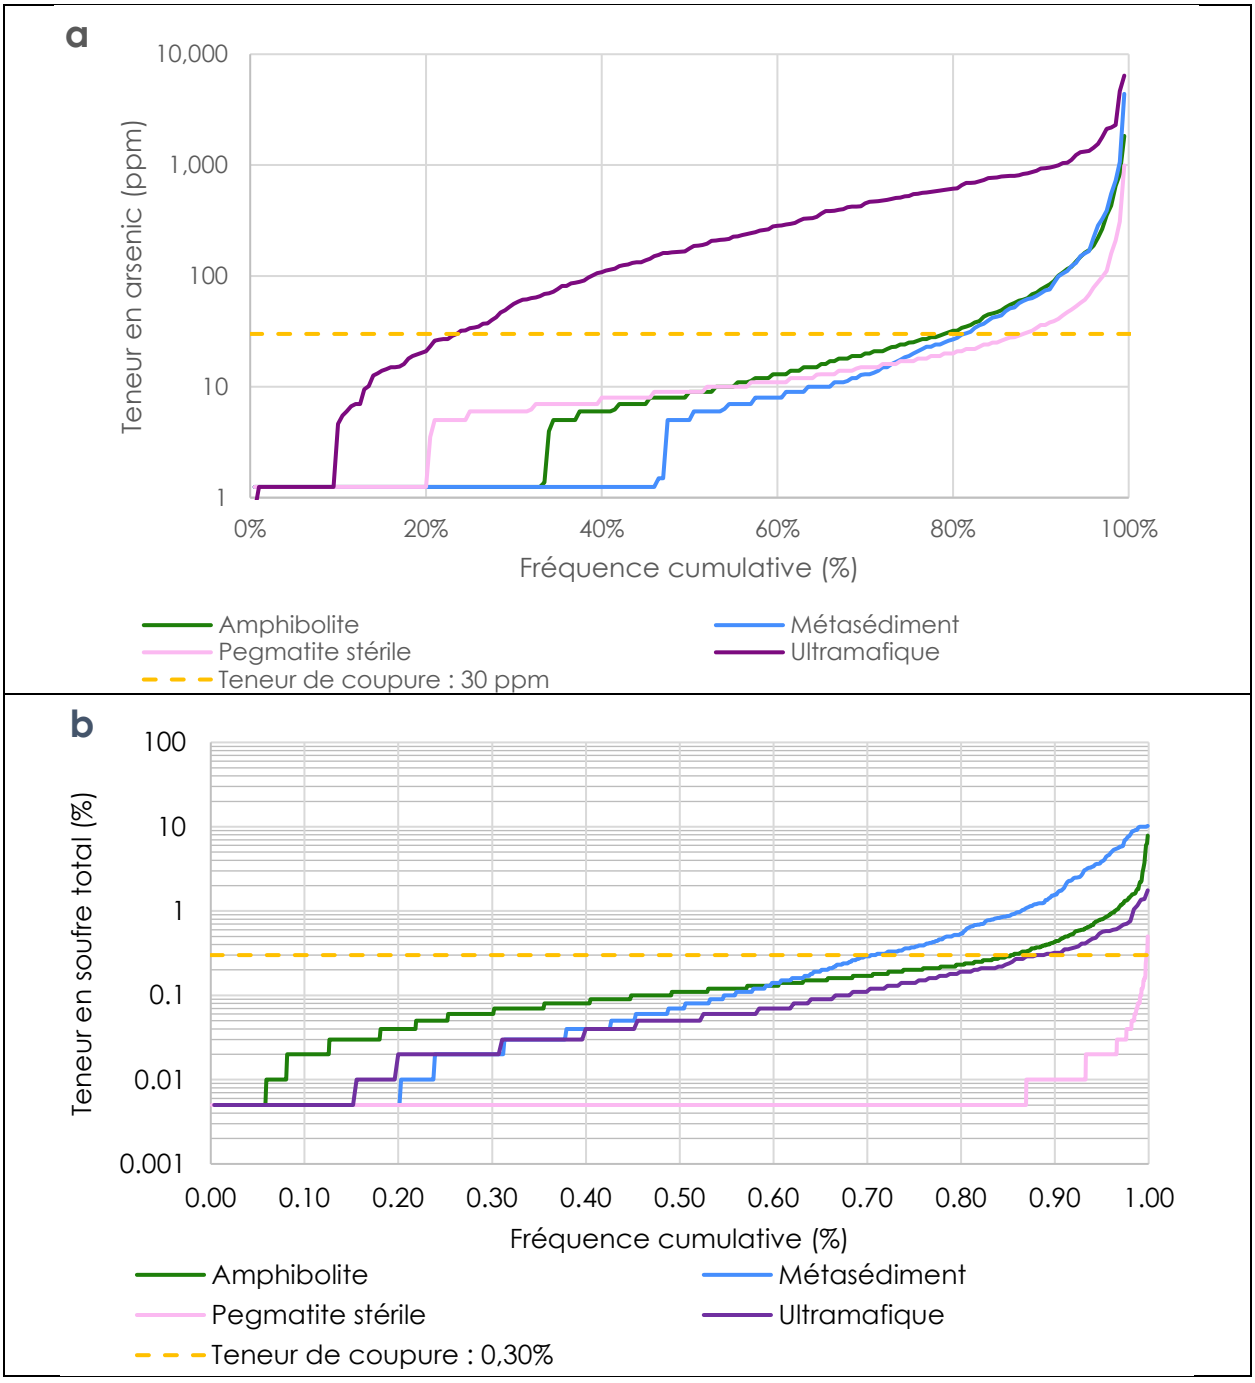

Figure 4. Fréquence cumulative des teneurs en arsenic et en soufre total des roches stériles dans la base de données des trous de forage

Tableau 7. Résumé des matériaux dépassant les seuils limites pour l'arsenic et le soufre total

Lithologie	Total des stériles (Mt)[1]	Dépassement du seuil limite d'arsenic		Dépassement de la limite totale de soufre	
		Masse (Mt)	%	Masse (Mt)	%
Amphibolite	61,0	12,8	21 %	8,8	14 %
Métasédiments	60,5	11,2	19 %	17,6	29 %
Pegmatite stérile	10,4	1,25	12 %	0,02	0 %
Ultramafique	23,1	17,6	77 %	2,6	11 %
Total	**155**	**42,9**	**28 %**	**29,0**	**19 %**

[1]Les quantités de stériles par lithologie ont été extraites du plan d'extraction LOM fourni par G Mining (G Mining, 2025).

Tableau 8. Résumé des caractéristiques de Stockpile-001 et Stockpile-002

Composition des haldes[1]		Stockpile-001	Stockpile-002
Masse (Mt)	**Amphibolite**	21,2	27,4
	Métasédiments	19,5	25,4
	Pegmatite stérile	3,32	5,12
	Ultramafique	0,214	22,6
	Résidus miniers	-	54
	Masse totale	**44,2**	**80,6**
Bassin versant (ha)		**80**	**218**

[1]Les capacités de stockage des haldes ont été fournies par Atkins, et les quantités par lithologie ont été déterminées sur la base du calendrier d'exploitation fourni par G Mining (G Mining, 2025).

2.9.6 *Simulations de modèles*

Des modèles géochimiques ont été développés pour prédire les concentrations de COPC dans les Stockpile-001 et -002 au fil du temps. Comme décrit dans la section précédente, le Stockpile-001 est composé uniquement de stériles, tandis que le Stockpile-002 contiendra un mélange de stériles et de résidus. Le comportement géochimique des deux types de matériaux a été simulé. Le modèle géochimique a été simulé à l'aide des paramètres des facteurs d'ajustement supposés résumés dans **Tableau 9**.

Table 9. Résumé des valeurs des paramètres d'ajustement du modèle, justification et références

Paramètre (symbole ; unités)	Stériles	Résidus	Justification/Référence
Taux de percolation (q_p; l/m²/an)	591		Hypothèse technique tirée de la conception d'Atkins (AtkinsRéalis, 2025) : toutes les précipitations incidentes sont supposées s'infiltrer à travers le matériau et être entièrement récupérées dans le bassin de collecte.
Densité apparente (Gs ; kg/m³)	2000		Conforme aux estimations d'Atkins (AtkinsRéalis, 2025)
Facteur d'échelle de taille des particules (S_{PSD}; sans unité)	0,05	1	Calculé sur la base des estimations de G Mining concernant la taille des particules des matériaux dynamités (G Mining, 2025) ; conforme à la littérature (Stockwell et al., 2006 ; Dawson, 1994 ; Ecometrix, 2014).
Facteur d'échelle de température ($S_{Temp.}$; sans unité)	0,3	0,3	Calculé selon la loi d'Arrhenius (**équation 5**), à partir d'estimations conservatrices de la température, conformément aux recommandations du MEND.
Facteur d'échelle d'isolation hydraulique (S_{HI}; sans unité)	0,1	0,3	Estimations basées sur la littérature (Rescan, 2013 ; Lorax, 2014 ; Stantec, 2017)

2.9.6.1 *Modélisation des stériles*

Un modèle basé sur Monte Carlo intégrant les hypothèses et les facteurs d'échelle décrits dans la section 4.3 ci-dessus a été développé à partir de la conception de la halde, du modèle de ressources dans la fosse et du calendrier fournis par Atkins et G Mining (AtkinsRéalis, 2025 ; G Mining, 2025), ainsi que par la DHDB contenant 4 678 échantillons de carottes de roches stériles.

Cette approche a permis une distribution spatiale aléatoire des lithologies et des caractéristiques de lixiviation de l'arsenic associées, d'une manière qui reflète la variabilité et les proportions observées dans le modèle de ressources dans la fosse. En conséquence, le modèle capture la gamme probabiliste et la distribution des paramètres géochimiques. La méthode Monte Carlo s'appuie sur l'ensemble complet des données de la DHDB et pondère chaque valeur en fonction de sa fréquence et de son occurrence lithologique telles qu'observées sur le terrain.

Le modèle a simulé le placement progressif des stériles dans les haldes conformément au calendrier d'extraction de la durée de vie de la mine (LOM) fourni par G Mining, en supposant une distribution aléatoire des teneurs totales en arsenic et en soufre dans le modèle de bloc d'extraction, avec une ségrégation appliquée selon le seuil précédemment défini.

Le modèle a été exécuté dans 1 000 simulations, ce qui a permis d'évaluer la variabilité probabiliste des résultats en fonction de la distribution hétérogène des types lithologiques et des caractéristiques de lixiviation.

2.9.6.2 *Modélisation des résidus miniers*

La modélisation des résidus miniers est appliquée un seul type de matériau, par conséquent, une simulation de type Monte Carlo n'était pas nécessaire.

Les caractéristiques de résidus simulées ont été obtenues en combinant les charges COPC provenant de CV5-CL-1 (flottants), CV5-CL-2 (moyens) et CV5-CL-4 (dérivation), avec des proportions pondérées de 52 %, 26 % et 22 %, respectivement.

La quantité de matériaux simulée a été progressivement augmentée entre 2030 et 2049 afin de reproduire le calendrier de production minière sur la durée de vie de la mine (LOM) élaboré par G Mining, pour atteindre une capacité maximale de 54 Mt.

Les trois constituants simulés – l'antimoine, l'arsenic et le lithium – correspondent aux COPC les plus mobiles identifiés lors de la phase de criblage, c'est à dire ceux qui sont non soumis à des contrôles de solubilité liés au pH ou à l'alcalinité. L'absence de contrôle de la solubilité est une hypothèse conservatrice du modèle, car d'autres contrôles, tels que le mécanisme de sorption, peuvent avoir lieu sur le terrain.

3.0 Résultats de la caractérisation géochimique

3.1 Bilan acide-base

Des essais ABA ont été effectués sur les 350 échantillons collectés afin de déterminer leur AP et leur NP et d'identifier les matériaux pouvant être identifiés comme PAG. Les tableaux résumant les résultats ABA sont fournis dans l'**Annexe B**.

3.1.1 Analyse de la spéciation du carbone

Figure 5 montre que la relation entre le carbone CO_3 et le carbone total est bien corrélée (R^2 = 0,97) et généralement bien en dessous de la ligne de référence 1:1 (en pointillés), avec une pente de la ligne de régression de 0,90, ce qui suggère que la majeure partie du carbone se présente sous forme de carbonate qui participe probablement au NP. Deux échantillons de métasédiments se distinguent comme des valeurs aberrantes avec des rapports CO_3/carbone total de 60 % ou moins, ce qui suggère la présence d'espèces de carbone autres que les carbonates et qui ne participeront pas efficacement au NP. Dans l'ensemble, la teneur totale en carbone des échantillons constitue un prédicteur valable de la teneur en carbonate et pourrait être utilisée pour la caractérisation ABA des échantillons.

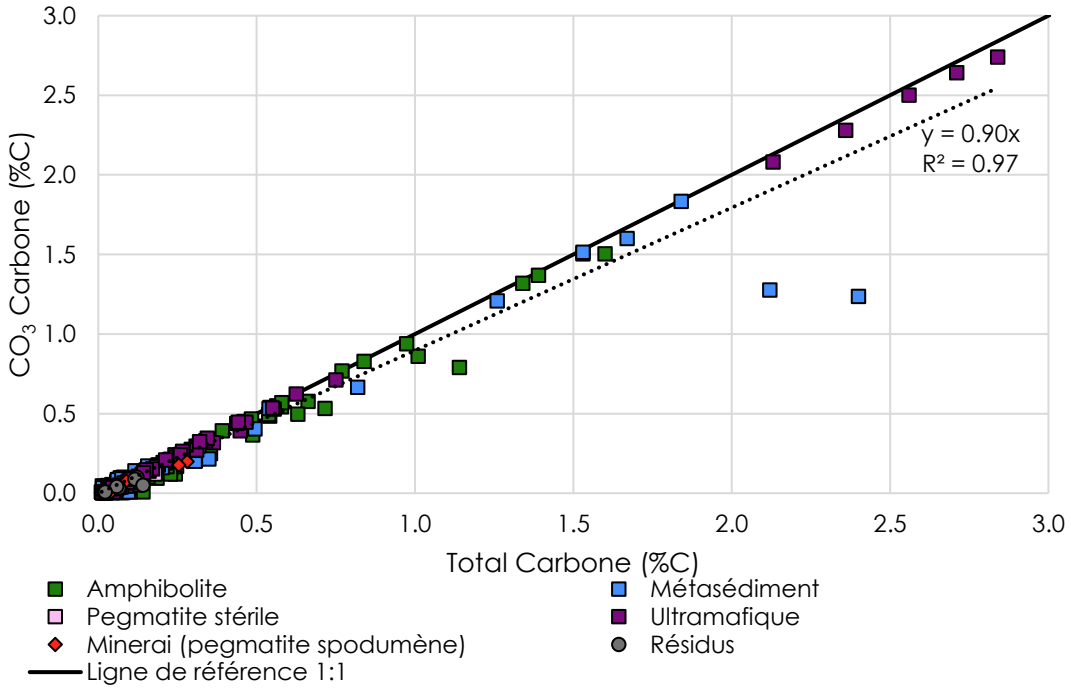

Figure 5: Relation entre le carbone carbonaté et le carbone total

L'analyse des carbonates a montré que 81 échantillons se situaient à la limite inférieure ou en dessous de la limite de détection de l'instrument (0,025 % ou 0,04 % en CO_3, selon la mesure). Les matériaux dont la teneur en carbone était inférieure à la limite de détection comprenaient 9 échantillons d'amphibolite (7,0 %), 17 échantillons de métasédiments (16,8 %), 22 échantillons de

pegmatite stérile (66,7 %), 8 échantillons d'ultramafique (14,8 %), 21 échantillons de minerai de pegmatite spodumène (84,0 %) et 4 échantillons de résidus (30,8 %). Pour ces échantillons, les valeurs de carbone total , qui ont une limite de détection plus faible, ont été utilisées à des fins de classification.

3.1.2 Analyse de la spéciation du soufre

Figure 6 montre la corrélation entre la concentration totale en soufre et le soufre sous forme de sulfure. L'analyse de régression entre le soufre total et le soufre sous forme de sulfure a un R^2 = 0,99 et une pente de 0,89, ce qui indique une bonne concordance entre les teneurs en soufre sous forme de sulfure et en soufre total. Ce résultat suggère que la majeure partie du soufre présent dans les échantillons se trouve probablement sous forme de sulfure et, par conséquent, que les teneurs totales en soufre constituent une approximation appropriée du soufre sous forme de sulfure.

Bien que la teneur totale en soufre varie considérablement, allant d'une limite de détection de 0,005 % à un maximum de 7,39 %, elle reste généralement faible, avec une moyenne de 0,35 %. Cela correspond à une teneur moyenne en soufre sous forme de sulfure de 0,29 %, allant d'une valeur inférieure à la limite de détection de 0,01 % à un maximum de 7,15 %.

Le type lithologique pegmatite, à savoir les stériles pegmatitiques, le minerai et les résidus, présente une forte proportion d'échantillons dont la teneur totale en soufre est inférieure à 0,04 %, avec respectivement 87,9 %, 88,0 % et 76,9 % des échantillons. Ces matériaux sont donc classés par défaut comme non PAG (non potentiellement générateurs d'acide). En revanche, les autres lithologies de stériles, à savoir l'amphibolite, le métasédiment et les matériaux ultramafiques, présentent des proportions nettement inférieures d'échantillons dont la teneur totale en soufre est inférieure à 0,04 %, avec respectivement 8,6 %, 32,7 % et 29,6 % (**Tableau 10**).

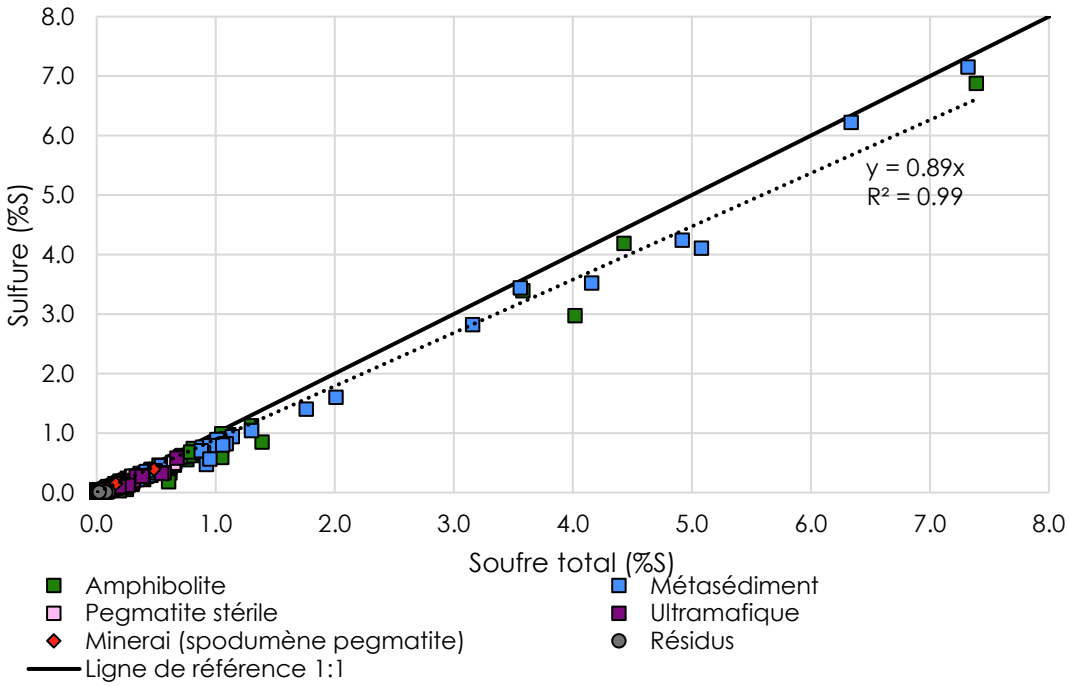

Figure 6. Relation entre soufre sulfure et soufre total

Table 10. Résumé des échantillons présentant une concentration totale en soufre inférieure à 0,04 % par type de matériau

Type de matériau	Total des échantillons	<0,04 % de soufre total (%)	
		n	%
Amphibolite	128	11	8,6 %
Métasédiment	101	33	32,7 %
Pegmatite stérile	33	29	87,9 %
Ultramafique	54	16	29,6 %
Total des stériles	**316**	**89**	**28,2 %**
Minerai (pegmatite spodumène)	25	22	88,0 %
Résidus miniers	9	7	77,8 %

3.1.3 Évaluation du potentiel de neutralisation et d'acidification

Figure 7 montre que, malgré une corrélation relativement bonne entre Sobek-NP et CO_3-NP (R^2=0,78), la plupart des points de données se situent en dessous de la ligne de référence 1:1 (en pointillés), avec une pente de la ligne de régression de 0,80. Le rapport CO_3-NP/Sobek-NP pour les échantillons de la plupart des types de matériaux est bien inférieur à ce coefficient de pente : 0,55 pour l'amphibolite, 0,60 pour les métasédiments, 0,27 pour la pegmatite stérile et le minerai de pegmatite spodumène, et 0,36 pour les résidus miniers.

Ces résultats suggèrent qu'une partie importante du potentiel de neutralisation des échantillons est due à des phases minérales autres que les carbonates. En revanche, les échantillons ultramafiques se distinguent par un rapport CO_3-NP/Sobek-NP moyen de 0,88, ce qui indique que les carbonates jouent un rôle plus important dans le potentiel de neutralisation de cette lithologie.

De plus, deux échantillons ultramafiques et un échantillon métasédimentaire présentent des valeurs de CO_3-NP nettement supérieures à leurs valeurs Sobek-NP respectives. Cette observation suggère la présence, dans ces échantillons particuliers, d'espèces carbonatées (par exemple, sidérite, ankérite ou calcite ou dolomite encapsulée) qui ne fournissent pas de NP efficace.

Compte tenu des rapports CO_3-NP/Sobek-NP généralement plus faibles observés dans la plupart des types de matériaux, ainsi que de la présence d'espèces carbonatées qui ne contribuent pas efficacement à la neutralisation de l'acide, Sobek-NP a été retenu comme indicateur privilégié du potentiel de neutralisation pour la présente analyse géochimique.

Représentation graphique de Sobek-NNP en fonction de Sobek-NPR (**Figure 8**) montre que tous les échantillons sauf un dépassant le critère NNP (NNP < 20 $kgCaCO_3/t$; ligne verte) dépassent également le critère NPR (NPR < 2 ; ligne orange). Cependant, une grande partie des échantillons qui satisfont au critère NPR (83,7 % de tous les échantillons) ne satisfont pas au critère NNP (27,4 % de tous les échantillons). Cette divergence s'explique par le fait que de nombreux échantillons présentent à la fois des valeurs NP et AP inférieures à 20, ce qui les classe comme PAG selon le critère NNP, à moins que leur teneur totale en soufre ne soit inférieure à 0,04 %.

Contrairement au NNP, qui tend à classer par défaut les matériaux présentant à la fois un faible NP et un faible AP comme PAG, le NPR fournit une mesure relative de la capacité de neutralisation acide qui reste significative même à des valeurs absolues faibles. Compte tenu de cette divergence, le NPR a été retenu comme mesure privilégiée pour la classification ABA, car il fournit des informations à la fois sur le NP et l'AP des échantillons, contrairement au NNP, qui ne fournit que des informations sur le NP.

Représentation graphique de Sobek-NPR en fonction du soufre total (**Figure 9**) révèle une tendance générale à la baisse des valeurs NPR avec l'augmentation de la teneur en soufre. Tous les échantillons dont la teneur totale en soufre est inférieure à 0,04 % (n = 118 ; 33,7 %) présentent des valeurs Sobek-NPR bien supérieures au seuil critique de 2. En outre, 99,7 % des échantillons dont la teneur en soufre est inférieure à 0,30 % présentent également des valeurs NPR supérieures à 2 et peuvent donc être classés comme non PAG. Au total, 57 échantillons (16,3 %) entrent dans la catégorie PAG, c'est-à-dire qu'ils se situent en dessous du seuil NPR de 2 et sont mis en évidence dans l'encadré orange.

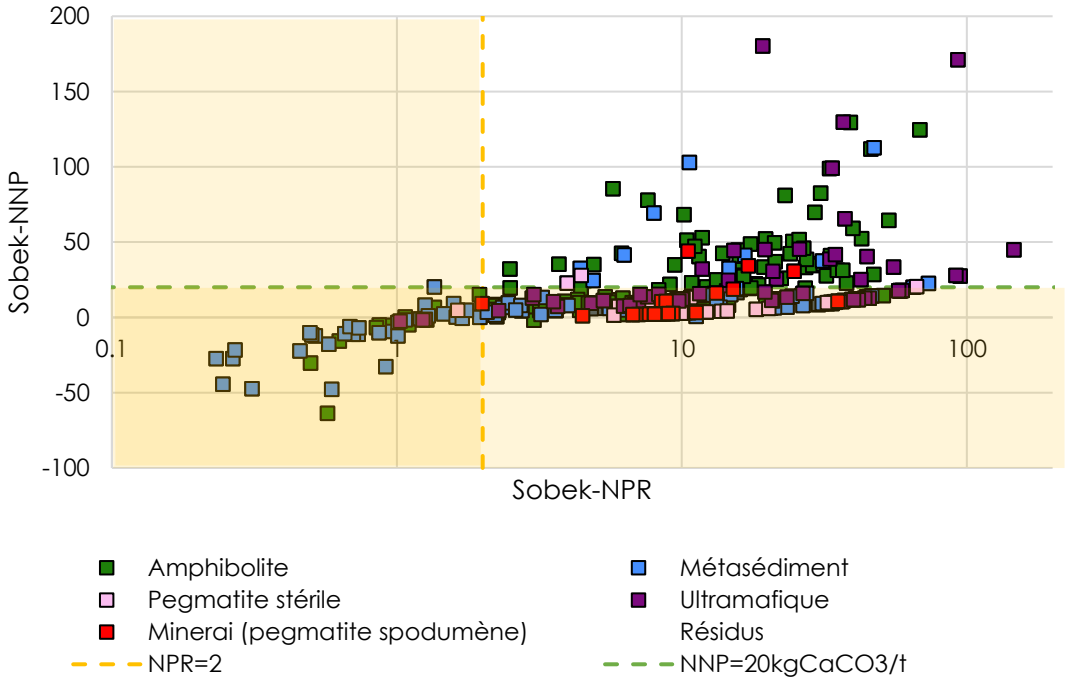

Figure 8: Relation entre Sobek-NNP et Sobek-NRP

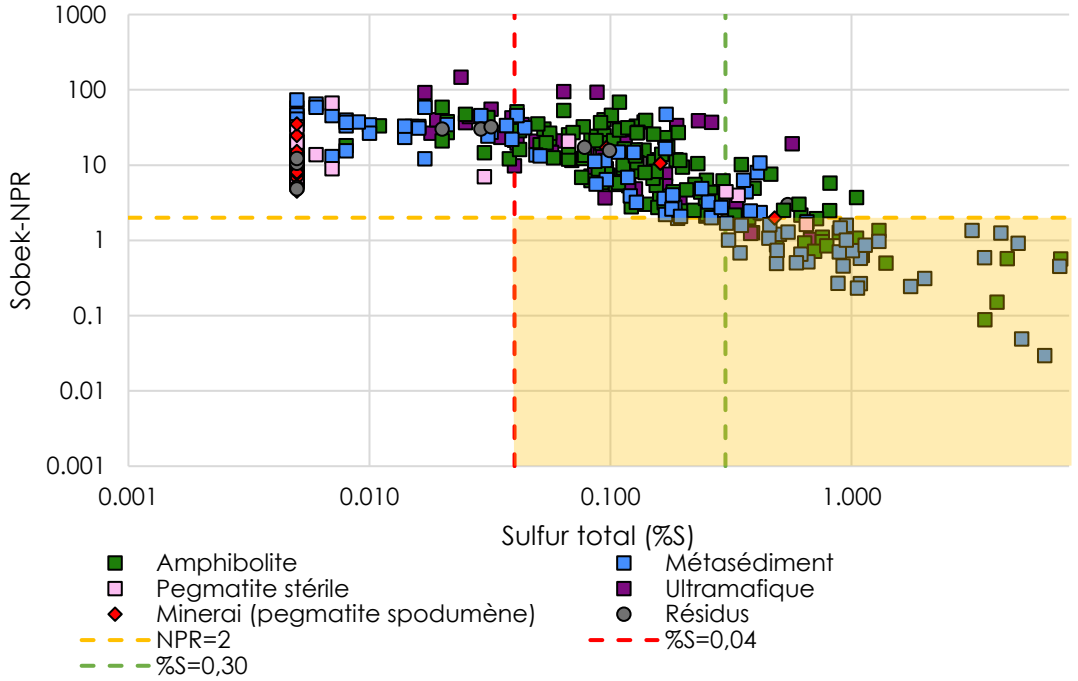

Figure 9: Relation entre NPR et soufre total

3.1.4 Résumé et interprétation

Afin d'étayer l'interprétation ABA des résultats des essais statiques, un tableau récapitulatif complet a été établi, compilant les paramètres clés pour tous les types de matériaux (**Tableau 11**). Ce tableau comprend une distribution statistique des valeurs totales de soufre, de soufre sulfuré, de carbone total, de teneur en carbonate, Sobek-NP, Sulfide-AP et Sobek-NPR.

L'analyse ABA a montré que le carbone total était fortement corrélé à la teneur en carbonate (R^2 = 0,97), ce qui suggère qu'il pourrait servir de bon indicateur du CO_3-NP. Cependant, le CO_3-NP n'était pas systématiquement corrélé au Sobek-NP (R^2 = 0,78 ; pente de régression = 0,80), les rapports CO_3-NP/Sobek-NP variant de 0,27 à 0,88 selon la lithologie. Cela indique qu'une partie importante des NP est probablement associée à des minéraux non carbonatés, tels que les silicates (par exemple, l'olivine, le feldspath, le pyroxène, l'amphibole) (Lawrence et Scheske, 1997 ; Jambor et al., 2002). Par conséquent, le carbone total et le carbone carbonaté semblent être de mauvais prédicteurs du NP. Dans les futurs essais statiques, le Sobek-NP devrait rester la méthode privilégiée pour la caractérisation du NP.

À l'inverse, le soufre total s'est révélé être un indicateur fiable, bien que légèrement prudent, du soufre sulfuré (R^2 = 0,99 ; pente de régression = 0,89), avec une moyenne de 83 % du soufre présent sous forme de sulfures. Les concentrations totales en soufre étaient généralement faibles, avec une moyenne de 0,35 % pour tous les types de matériaux. De plus, 28,2 % des échantillons de stériles, 88,0 % des échantillons de minerai et 77,8 % des échantillons de résidus miniers présentaient une teneur totale en soufre inférieure au seuil de 0,04 %.

De plus, une grande partie des échantillons qui répondaient au critère NPR (83,7 % de tous les échantillons) ne répondaient pas au critère NNP (seulement 27,4 % de tous les échantillons). Cette divergence s'explique par le fait que de nombreux échantillons avaient des valeurs NP inférieures à 20, ce qui les classait automatiquement comme PAG selon le critère NNP. Compte tenu de cette incohérence, le NPR a été retenu comme mesure privilégiée pour la classification ABA. Cette approche est considérée comme plus appropriée pour l'ensemble de données actuel, dans lequel de nombreux échantillons présentent une faible teneur en soufre et un potentiel de neutralisation modéré.

Parmi les 350 échantillons prélevés, 57 (16,3 %) ont été classés comme PAG. Les lithologies de roches stériles amphibolites (n = 16 ; 12,5 %) et métasédimentaires (n = 36 ; 35,6 %) présentaient les proportions les plus élevées d'échantillons PAG, tandis que les roches stériles pegmatitiques et ultramafiques ne présentaient respectivement qu'un (3,0 %) et trois (5,6 %) échantillons PAG. De plus, tous les échantillons de résidus ont été classés comme non PAG en raison de leur teneur totale en soufre négligeable (0,04 %), et un seul échantillon de minerai (4,0 %) a été classé comme PAG. **Tableau 12** résume le nombre d'échantillons PAG par type de lithologie.

L'interprétation des résultats a montré que les échantillons de stériles contenant moins de 0,30 % de soufre total étaient à 99,7 % exempts de PAG. Une valeur seuil de 0,30 % de soufre total pourrait donc être envisagée pour la séparation des matériaux contenant des PAG.

3.2 Constituants extractibles et potentiel de lixiviation

Les résultats des essais de lixiviation effectués sur les échantillons sélectionnés ont été évalués conformément aux lignes directrices du MELCCFP.

Afin de mettre en évidence les enrichissements potentiels en COPC des matériaux, les résultats du essais de lixiviation à l'eau régale ont été comparés à la concentration moyenne de la croûte continentale. (Rudnick et Gao, 2014) ainsi qu'aux informations générales sur la province géologique supérieure fournies à l'annexe 1 du *Guide d'intervention – protection des sols et réhabilitation des terrains contaminés* (MELCCFP, 2021).

Comme indiqué précédemment, il convient de noter que les teneurs moyennes de la croûte terrestre se réfèrent à la teneur totale (digestion totale) et que les teneurs extractibles se réfèrent à la teneur partielle (digestion partielle). Par conséquent, les comparaisons doivent être effectuées avec prudence. Cependant, les teneurs extractibles peuvent être comparées aux critères A présentés dans le guide MELCCFP (2021).

Les résultats des essais de lixiviation SPLP et CTEU-9 ont été comparés aux *Critères de qualité pour la protection de la vie aquatique – effet aigu* (CVAA) tirés des Critères de qualité des eaux de surface (CQES) fournis par le MELCCFP. Les valeurs réglementaires pour certains éléments (par exemple, le cadmium, le manganèse) dépendent de la dureté du système aquatique récepteur, tandis que pour l'aluminium (Al), elles dépendent également du carbone organique dissous (concentration en COD) et du pH. Les valeurs réglementaires ont été calculées en supposant une concentration en COD de 5 mg/L, un pH de 6 et une dureté de 5 mg/L.

Les résultats des essais de lixiviation TCLP ont été comparés à la directive 019 – annexe 2 sur les caractéristiques des résidus miniers (à haut risque).

Les tableaux récapitulatifs des résultats des essais de lixiviation et des réglementations figurent à l'**Annexe C**.

3.2.1 Constituants extractibles

Une comparaison des éléments enrichis par rapport à 10 fois la teneur moyenne de la croûte continentale est fournie dans **Tableau 13** pour mettre en évidence les enrichissements en métaux et métalloïdes supérieurs aux niveaux naturels.

L'arsenic était l'élément le plus enrichi, avec 59 % des échantillons de stériles dépassant 10 fois l'abondance crustale. Un enrichissement élevé en arsenic a été particulièrement observé dans les stériles ultramafiques (n = 54 ; 100 %), les amphibolites (n = 73 ; 57 %) et les métasédiments (n = 11 ; 33 %).

L'antimoine et le lithium étaient également très enrichis, les échantillons enrichis correspondant respectivement à 50 % et 40 % du total des échantillons de stériles. L'enrichissement en antimoine était particulièrement notable dans les roches ultramafiques (n = 48 ; 89 %), les amphibolites (n = 65 ; 51 %) et les stériles pegmatitiques (n = 33 ; 33 %). Le lithium était le plus abondant dans les roches stériles pegmatitiques (n = 69 ; 68 %), suivies des roches stériles ultramafiques (n = 17 ; 31 %) et amphibolites (n = 38 ; 30 %).

D'autres éléments ont dépassé 10 fois leur abondance dans la croûte terrestre uniquement dans un nombre limité d'échantillons. Le bismuth a atteint 45 % des métasédiments (n = 15), le nickel a dépassé le seuil dans 22 % des stériles ultramafiques (n = 12) et le bore l'a dépassé dans 6 % des échantillons ultramafiques (n = 3 ; 6 %). Les autres éléments, notamment le cadmium, le cuivre, le plomb, le mercure, le molybdène, l'étain, l'uranium et le zinc, ont montré un enrichissement limité dans l'ensemble des stériles.

Le minerai de pegmatite spodumène et les résidus miniers présentent généralement moins d'échantillons dépassant 10 % d'abondance crustale, à l'exception notable de l'arsenic (n = 13 ; 52 % dans le minerai ; n = 5 ; 56 % dans les résidus miniers) et de l'antimoine (n = 13 ; 52 % dans le minerai ; n=8 ; 89 % dans les résidus), et pour le bore à la fois dans le minerai (n=13 ; 52 %) et dans les résidus (n=4 ; 44 %).

Il convient de noter que les résultats de la digestion à l'eau régale ne représentent qu'une partie du contenu total, les dépassements de la teneur moyenne de la croûte terrestre sont susceptibles d'être plus importants et présents dans un plus grand nombre d'échantillons.

Une comparaison des concentrations en métaux et métalloïdes obtenues par extraction à l'eau régale par rapport aux critères A de la province géologique supérieure est fournie dans **Tableau 14** pour mettre en évidence les contenus extractibles au-dessus des niveaux naturels de fond.

L'arsenic était l'élément le plus enrichi, avec 78 % des échantillons de stériles dépassant le critère A. Un enrichissement élevé en arsenic a été particulièrement observé dans les stériles ultramafiques (n=54 ; 100 %), les stériles de pegmatite (n=25 ; 76 %), les amphibolites (n=98 ; 77 %) et les métasédiments (n=70 ; 69 %).

Le cuivre et le nickel étaient également fréquemment enrichis, observés respectivement dans 45 % et 32 % des échantillons de stériles totaux. L'enrichissement en cuivre était particulièrement notable dans l'amphibolite (n = 98 ; 77 %), l'ultramafique (n = 24 ; 44 %) et les métasédiments (n =

18 ; 18 %). Le nickel dépassait le critère A principalement dans les roches ultramafiques (n = 53 ; 98 %), suivies par l'amphibolite (n = 36 ; 28 %) et les métasédiments (n = 12 ; 12 %).

Le chrome et le cobalt ont montré un enrichissement significatif dans les stériles ultramafiques, 98 % des échantillons ultramafiques dépassant le critère A pour le chrome (n = 53) et 65 % pour le cobalt (n = 35).

D'autres éléments n'ont dépassé les critères A que dans un nombre limité d'échantillons. Mis à part l'arsenic, le cuivre, le nickel et le chrome, des éléments tels que l'étain, le baryum, le cadmium, le plomb, le manganèse, le mercure, le molybdène, l'argent et le zinc ont montré un enrichissement plus limité dans l'ensemble des stériles. L'étain était particulièrement enrichi dans les métasédiments (n = 12 ; 12 %) et l'amphibolite (n = 7 ; 5 %).

Le minerai de pegmatite spodumène et les résidus miniers présentaient généralement peu d'échantillons dépassant les critères A, à l'exception de l'arsenic (n = 22 ; 88 % dans le minerai ; n = 9 ; 100 % dans les résidus miniers), du chrome (n = 3 ; 12 % dans le minerai ; n = 5 ; 56 % dans les résidus miniers) et du nickel dans les résidus miniers (n = 3 ; 33 %).

[1]Annexe 1 – Critères génériques A (niveaux de fond) pour les métaux et métalloïdes dans les sols de la province géologique du Supérieur (MELCC, 2021)

3.2.2 Essais SPLP

Les résultats du pH obtenus lors des essais de lixiviation SPLP ont présenté une valeur finale moyenne de 8,10 et sont restés conformes aux directives sur la qualité des eaux de surface pour les effluents miniers (6,0 à 9,5) en cas d'exposition chronique du CQES pour tous les échantillons, à l'exception d'un échantillon de métasédiments (CV5-MS-202) présentant une valeur de 5,72.

Une comparaison des résultats des essais de lixiviation SPLP avec les critères CVAA est fournie dans **Tableau 16** pour mettre en évidence les éléments dépassant les seuils réglementaires spécifiques au site.

L'aluminium était l'élément qui dépassait le plus souvent le critère de la CVAA, avec 79 % des échantillons de stériles totales dépassant 0,18 ppm. Des dépassements élevés de la teneur en aluminium ont été observés dans tous les types de stériles, y compris l'amphibolite (n = 121 ; 95 %), les métasédiments (n = 89 ; 88 %), la pegmatite stérile (n = 28 ; 85 %) et les roches ultramafiques (n = 12 ; 22 %).

L'arsenic a dépassé le critère de la CVAA dans une petite partie des échantillons (6 % du total des stériles), principalement dans les stériles ultramafiques (n = 17 ; 31 %), avec des dépassements très limités dans l'amphibolite (n = 2 ; 2 %) et la stérile pegmatitique (n = 1 ; 1 %).

Les autres éléments dépassant les critères CVAA dans un nombre limité d'échantillons comprennent l'antimoine, le cuivre, le béryllium, le plomb, l'uranium et le zinc. L'antimoine dépassait le critère dans les échantillons de métasédiments (n = 1 ; 1 %) et d'ultramafiques (n = 1 ; 2 %), tandis que le cuivre dépassait le critère dans 3 % des échantillons de roches stériles, notamment dans les amphibolites (n = 3 ; 2 %), les métasédiments (n = 4 ; 4 %) et la pegmatite stérile (n = 4 ; 12 %). Les dépassements de béryllium ont été observés essentiellement dans la pegmatite stérile (n = 4 ; 12 %). Le plomb et le fer ont dépassé les critères dans très peu d'échantillons, avec seulement quelques occurrences isolées, l'uranium a dépassé le critère de la CVAA dans deux échantillons de pegmatite stérile (n=2; 6 %) et le zinc a dépassé le seuil de la CVAA dans 3 % des échantillons de stériles, principalement dans l'amphibolite (n=5; 4 %), la pegmatite stérile (n=3; 9 %) et les métasédiments (n=2; 2 %).

Le minerai et les résidus ont présenté globalement moins de dépassements, à l'exception notable de l'aluminium (n = 15 ; 60 % dans le minerai ; n = 8 ; 89 % dans les résidus) et du cuivre (n = 3 ; 12 % dans le minerai ; n = 3 ; 33 % dans les résidus), ainsi que du zinc dans les résidus (n = 2 ; 22 %).

Tableau 16 présente les résultats des essais SPLP comparés aux critères MDMER et D019. Des dépassements des critères MDMER/D019 ont été observés uniquement pour l'arsenic et le fer. L'arsenic (0,10 mg/L) a été dépassé dans 12 échantillons d'amphibolite (n = 128 ; 9 %), 5 métasédiments (n = 101 ; 5 %), 1 échantillon de pegmatite stérile (n = 33 ; 3 %) et 36 échantillons ultramafiques (n = 54 ; 67 %). Au total, 54 échantillons de stériles (n = 316 ; 17 %) dépassaient le critère, ainsi que 4 échantillons de minerai de pegmatite spodumène (n = 25 ; 16 %) et 3 échantillons de résidus (n = 9 ; 33 %). Le fer (3 mg/L) dépassait le critère dans un seul échantillon de métasédiment (n = 101 ; 1 %). Le fer, dont le critère est de 3 mg/L, n'a dépassé la limite que dans un seul échantillon de métasédiment (n = 101 ; 1 %). Aucun dépassement n'a été enregistré dans les autres types de matériaux.

Table 15. Résumé des échantillons présentant des résultats des essais de lixiviation SPLP dépassant les valeurs réglementaires de la CVAA

3.2.3 essais de lixiviation CTEU-9

Les résultats de pH obtenus à partir des essais de lixiviation CTEU-9 se situaient entre 4,67 et 9,77, avec 16 échantillons de stériles et un échantillon de minerai dépassant la limite supérieure de pH de 9,5, et deux échantillons, dont un amphibolite (VIS-CV5-AMP-106) et un métasédiment (VIS-CV5-MS-202), dépassant la limite inférieure avec des valeurs de pH respectives de 5,67 et 4,67.

Une comparaison des résultats des essais de lixiviation SPLP avec les critères CVAA est fournie dans **Tableau 17** pour mettre en évidence les éléments dépassant les seuils réglementaires spécifiques au site.

L'aluminium était l'élément qui dépassait le plus souvent le critère de la CVAA, avec 70 % des échantillons de stériles totales dépassant 0,28 ppm. Des dépassements élevés de la teneur en aluminium ont été observés dans tous les types de stériles, y compris les métasédiments (n = 84 ; 83 %), l'amphibolite (n = 97 ; 76 %), la pegmatite stérile/granite (n = 33 ; 100 %) et les roches ultramafiques (n = 8 ; 15 %). L'aluminium dépassait également le critère dans tous les échantillons de minerai de pegmatite spodumène (n = 25 ; 100 %) et dans la plupart des résidus (n = 8 ; 89 %).

L'arsenic dépassait le critère de la CVAA dans 37 % des échantillons de stériles, principalement dans les stériles ultramafiques (n = 50 ; 93 %) et les stériles pegmatitiques (n = 24 ; 73 %), avec des dépassements supplémentaires dans les amphibolites (n = 26 ; 20 %) et les métasédiments stériles (n = 16 ; 16 %). L'arsenic était présent dans tous les échantillons de résidus (n = 9 ; 100 %) et dans la plupart des échantillons de minerai (n = 19 ; 76 %).

D'autres éléments dépassant les critères CVAA dans une plus petite fraction des échantillons comprennent le cuivre, le béryllium, le lithium, l'antimoine, le fer, le cadmium et le plomb. Le cuivre dépassait le critère dans 33 % des échantillons de stériles, notamment dans les stériles pegmatitiques (n = 19 ; 58 %), les amphibolites (n = 37 ; 29 %), les stériles pegmatitiques/granitiques (n = 34 ; 34 %) et les roches ultramafiques (n = 13 ; 24 %). Le lithium dépassait le critère dans 51 % des échantillons de stériles, en particulier dans l'amphibolite (n = 69 ; 54 %), la pegmatite stérile (n = 63 ; 62 %) et les roches ultramafiques (n = 21 ; 39 %). L'antimoine dépassait le critère dans 21 % des échantillons de stériles, notamment dans les stériles ultramafiques (n = 36 ; 67 %), dans le minerai (n = 10 ; 40 %) et dans les résidus (n = 5 ; 86 %). Le béryllium dépassait le seuil principalement dans la pegmatite stérile (n = 13 ; 39 %), tandis que l'antimoine le dépassait principalement dans les roches ultramafiques (n = 21 ; 39 %). Le fer dépassait le critère dans 8 % des échantillons de roches stériles, principalement dans l'amphibolite (n = 7 ; 5 %) et la pegmatite stérile/granite (n = 12 ; 12 %). Le cadmium et le plomb dépassaient le critère CVAA dans très peu d'échantillons. Les dépassements pour le manganèse étaient négligeables.

Tableau 18 présente les résultats des essais CTEU-9 comparés aux critères MDMER/D019. Des dépassements ont été observés pour l'arsenic, le fer et le nickel. L'arsenic (0,10 ppm) a dépassé le critère dans 62 échantillons d'amphibolite (n = 128 ; 48 %), 37 échantillons de stériles pegmatitiques (n = 101 ; 37 %), 31 échantillons de stériles pegmatitiques (n = 33 ; 94 %) et 53 échantillons ultramafiques (n = 54 ; 98 %). Au total, 183 échantillons de stériles (n = 316 ; 58 %) dépassaient le critère, en plus de 25 échantillons de minerai de spodumène de

pegmatite (n = 25 ; 100 %) et 9 échantillons de résidus (n = 9 ; 100 %). Le fer (3 ppm) dépassait le critère dans 8 échantillons d'amphibolite (n = 128 ; 6 %), 15 échantillons de métasédiments (n = 101 ; 15 %), 3 échantillons de pegmatite stérile (n = 33 ; 9 %) et 6 échantillons ultramafiques (n = 54 ; 11 %). Cela représentait 32 échantillons de roches stériles (n = 316 ; 10 %) ainsi que 15 échantillons de minerai de pegmatite spodumène (n = 25 ; 60 %). Le nickel (0,25 ppm) dépassait le critère dans un seul échantillon ultramafique (n = 54 ; 2 %), sans dépassement dans les autres matériaux.

3.2.4 Essais de lixiviation TCLP

Des essais de lixiviation TCLP ont été réalisés selon les critères D019 pour les rejets miniers à haut risque, et les deux dépassements identifiés provenaient des stériles ultramafiques.

Deux échantillons ultramafiques, analysés au cours de la phase 1, ont affiché des résultats TCLP-arsenic supérieurs au critère D019 de 5 mg/L, avec des valeurs respectives de 5,80 et 7,58 mg/L. Cependant, comme ces échantillons ont été classés comme non PAG, ils ne sont pas soumis à la classification « à haut risque » selon les critères du Québec. Ces deux échantillons avaient été sélectionnés spécifiquement dans la DHDB en raison de leur teneur élevée en arsenic sous forme de peroxyde de sodium.

3.2.5 Résumé et interprétation

Un résumé des métaux (métalloïdes) enrichis et des COPC identifiés à partir des différents essais statiques réalisés dans le cadre de l'étude sur les essais statiques est présenté dans **Tableau 19**.

L'analyse des composants extractibles à l'eau régale a permis d'identifier un large éventail de composants enrichis par rapport à la teneur de la croûte continentale 10X et aux seuils de teneur extractible de la province géologique supérieure. Dans les deux cas, l'arsenic (As) a été identifié comme le composant le plus enrichi.

Les essais de lixiviation SPLP et CTEU-9 ont partiellement reflété les enrichissements observés dans les analyses extractibles à l'eau régale, avec des variations résumées dans **Tableau 19**. par exemple, le cobalt, l'étain, l'argent et le mercure ont été exclus de la liste des constituants mis en évidence par les essais de lixiviation SPLP et CTEU-9. L'aluminium a présenté le plus grand nombre de dépassements, avec respectivement 267 et 255 occurrences dans les essais SPLP et CTEU-9, suivi par l'arsenic dans les essais SPLP (20 occurrences) et le lithium (191 occurrences), puis l'arsenic (144 occurrences) dans les essais CTEU-9. Plusieurs autres métaux ont également été mis en évidence dans les deux essais, notamment le cuivre, le zinc et le béryllium, tandis que des dépassements supplémentaires n'ont été identifiés que dans les essais CTEU-9, notamment pour le fer, le cadmium, le manganèse et le nickel. Enfin, l'antimoine et l'uranium ont également été mis en évidence, ainsi qu'un seul dépassement pour le vanadium dans les essais CTEU-9.

Les résultats contrastés des essais SPLP et CTEU-9 en termes de dépassements et de constituants identifiés suggèrent que la taille des particules et le temps d'agitation ont été les principaux facteurs de mobilisation : le SPLP utilise des matériaux broyés à moins de 1 cm avec une agitation de 18 heures, tandis que le CTEU-9 utilise des matériaux broyés à 100 mesh (~150 µm) avec une agitation de 7 jours. En revanche, le pH plus faible du lixiviant SPLP (pH 4,2) par rapport au CTEU-9 (eau déionisée, pH 5,5-6) n'a pas amélioré de manière significative la mobilisation des constituants, ce qui indique que la plupart des échantillons ont conservé une capacité tampon suffisante pour limiter la lixiviation rapide des constituants sensibles au pH, tels que les métaux répertoriés.

Enfin, aucun échantillon ou composant « à haut risque » n'a été identifié sur la base de la classification ABA et des essais TCLP.

Table 19: Résumé des dépassements provenant des différents procédures d'essais statiques

Essai statique	Critère	paramètres
Eau régale	10 fois la teneur en croûte continentale	Arsenic (n=206), Antimoine (n=179), Lithium (n=128), Bismuth (n=40), Nickel (n=12), Cadmium (n=9), Argent (n=6), Zinc (n=4), Cuivre (n=2), Plomb (n=2), Mercure (n=2))
	Critères A	Arsenic (n=278), cuivre (n=143), nickel (n=105), cobalt (n=40), étain (n=31), zinc (n=9), cadmium (n=8), plomb (n=7), argent (n=6), mercure (n=2)
SPLP	CVAA	Aluminium (n=267), arsenic (n=20), cuivre (n=17), zinc (n=14), béryllium (n=6), antimoine (n=3), uranium (n=2), plomb (n=1)
	MDMER / D019	Arsenic (n=20), Fer (n=1)
CTEU-9	CVAA	Aluminium (n=255), Lithium (n=191), Arsenic (n=144), Cuivre (n=114), Zinc (n=102), Antimoine (n=82) ; Plomb (n=59), Uranium (n=49), Fer (n=26), Béryllium (n=21), Cadmium (n=3), Nickel (n=2), Manganèse (n=1), Vanadium (n=1)
	MDMER / D019	Arsenic (n=183), fer (n=32), nickel (n=1)
TCLP	D019 – Critères de risque élevé	Aucun[1]

[1]Deux échantillons de roches stériles ultramafiques non PAG sélectionnés dans le DHDB pour leur teneur élevée en arsenic sous forme de peroxyde de sodium présentaient des concentrations en arsenic TCLP supérieures au seuil D019 pour l'arsenic.

3.3 Essais cinétiques

Un programme d'essais cinétiques comprenant 15 HCT (plus un duplicata) et 5 colonnes de résidus (plus un duplicata) a été lancé à ce jour dans le cadre de ce programme de caractérisation géochimique. Les HCT ont été réalisés pendant plus de 100 semaines depuis avril 2023 et se poursuivent encore en juillet 2025. Les résultats présentés dans ce rapport s'appliquent aux 100 premières semaines. Le programme d'essais sur colonnes de résidus a été lancé en février 2025, et 20 semaines de données (11 rinçages) sont présentées dans le présent rapport.

Les échantillons soumis à l'essai HCT ont été sélectionnés sur la base des résultats des essais statiques afin d'inclure les différentes lithologies et types de matériaux et de couvrir un large éventail de potentiels de génération d'acide et de taux de lixiviation. Les paramètres chimiques présentés et interprétés dans cette section comprennent :

- Les critères physicochimiques tels que le pH et la conductivité électrique (conductivité) ;
- Les produits d'oxydation et de neutralisation, notamment le sulfate, le calcium et le magnésium – pour les HCT uniquement en tant que résidus miniers – ne présentaient aucun risque de génération d'acide ;
- Les COPC identifiés dans le cadre criblage via essais statiques et cinétiques.

Les tableaux récapitulant les résultats relatifs aux HCT et aux colonnes publicitaires sont présentés à l'**Annexe D**.

3.3.1 Essais en cellules humides

Figure 10 affiche la variation cinétique des paramètres physicochimiques, à savoir le pH (a) et la conductivité électrique (b).

a. Au départ, tous les HCT présentent des conditions alcalines modérées avec des valeurs de pH comprises entre 7,31 et 9,09. Au fil du temps, on observe une baisse générale du pH dans tous les HCT. À la semaine 100, les HCT CV5-WR-HCT-59, CV5-WR-HCT-39 et CV5-WR-HCT-36 tombent en dessous du seuil réglementaire de 6,0, avec des valeurs minimales atteignant 5,67 (CV5-WR-HCT-59) et 5,69 (CV5-WR-HCT-39). Les autres HCT se stabilisent dans une fourchette comprise entre 6,0 et 7,5.

b. La figure montre l'évolution de la conductivité (µS/cm) sur 100 semaines pour les 15 HCT. Au départ, les valeurs varient entre 27 (CV5-WR-HCT-59) et 154 µS/cm (CV5-WR-HCT-74), mais une forte baisse se produit au cours des 20 premières semaines, la conductivité tombant à 4-60 µS/cm selon la cellule. Au fil du temps, une stabilisation s'opère, mais à des niveaux variables : CV5-WR-HCT-50 (métasédiments) et CV5-WR-HCT-2 (amphibolite) se stabilisent à des valeurs plus élevées (~30-50 µS/cm), tandis que CV5-WR-HCT-64, CV5-WR-HCT-69 (pegmatite stérile) et CV5-WR-HCT-74, CV5-WR-HCT-76 (pegmatite spodumène, minerai) se stabilisent à des niveaux beaucoup plus bas (2-10 µS/cm). Une diminution de la conductivité indique généralement la libération de charges ioniques facilement disponibles à la surface des matériaux.

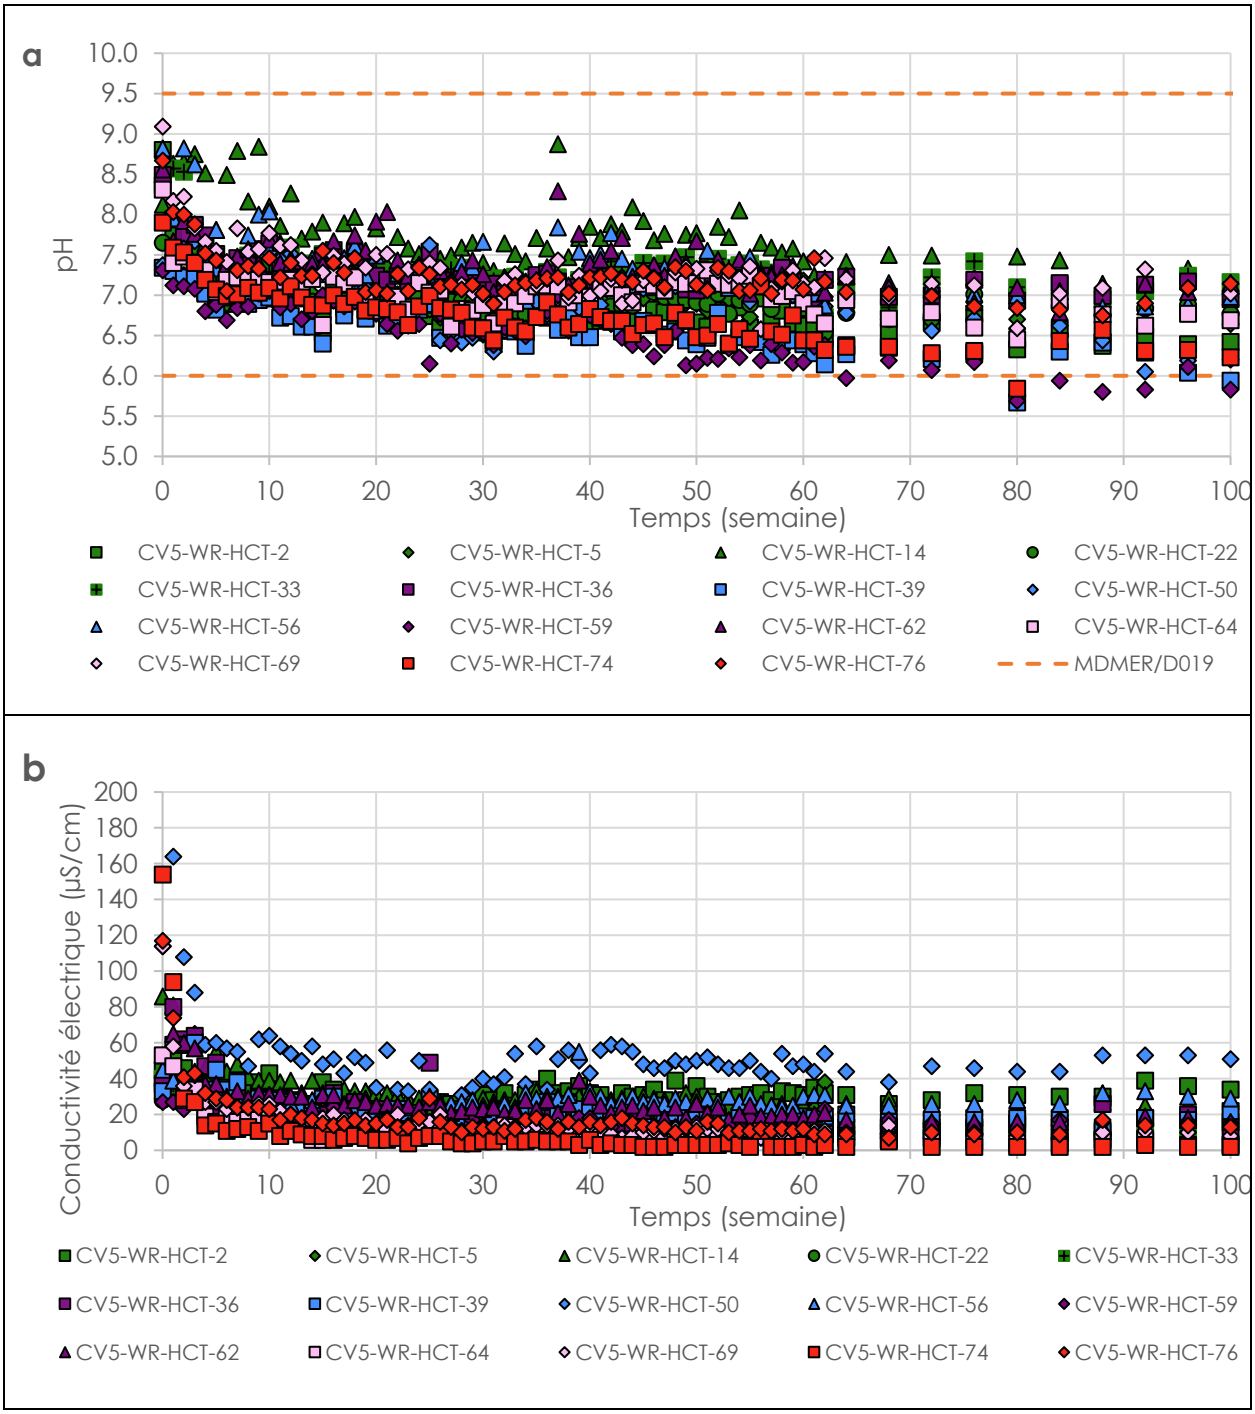

Figure 10. Tendances de la conductivité et du pH dans les essais en cellules humides

Les graphiques affichés dans **Figure 11** présenter les mesures d'alcalinité (a) et d'acidité (b) surveillées tout au long des 100 semaines d'essai.

a. Au départ, les valeurs d'alcalinité varient entre 27 (CV5-WR-HCT-59) et 164 mg $CaCO_3$/L (CV5-WR-HCT-50). Une baisse rapide se produit au cours des 20 premières semaines, les valeurs chutant à 4–60 mg $CaCO_3$/L selon la cellule. Au fil du temps, l'alcalinité se stabilise à différents niveaux : CV5-WR-HCT-50 (Métasédiments) reste plus élevé (~30–50 mg $CaCO_3$/L), tandis que CV5-WR-HCT-74 et CV5-WR-HCT-64 (pegmatite spodumène et pegmatite stérile, respectivement) se stabilisent à des niveaux beaucoup plus bas (2–10 mg $CaCO_3$/L). Une diminution de l'alcalinité indique une réduction du taux de tamponnage du matériau, reflétant une neutralisation acide continue.

b. L'acidité reste faible dans la plupart des HCT, avec des valeurs principalement égales ou inférieures à 2 mg $CaCO_3$/L pendant la majeure partie de la période de surveillance. Quelques cellules présentent de légères augmentations au fil du temps : CV5-WR-HCT-50 (Métasédiments) présente une augmentation progressive après la semaine 60, atteignant jusqu'à 17 mg $CaCO_3$/L à la semaine 100, tandis que CV5-WR-HCT-59 (Ultramafique) présente des fluctuations mineures, avec un pic à 9 mg $CaCO_3$/L. Ces augmentations suggèrent une génération d'acide dans des lithologies spécifiques, en particulier dans les HCT Métasédiments et Ultramafique.

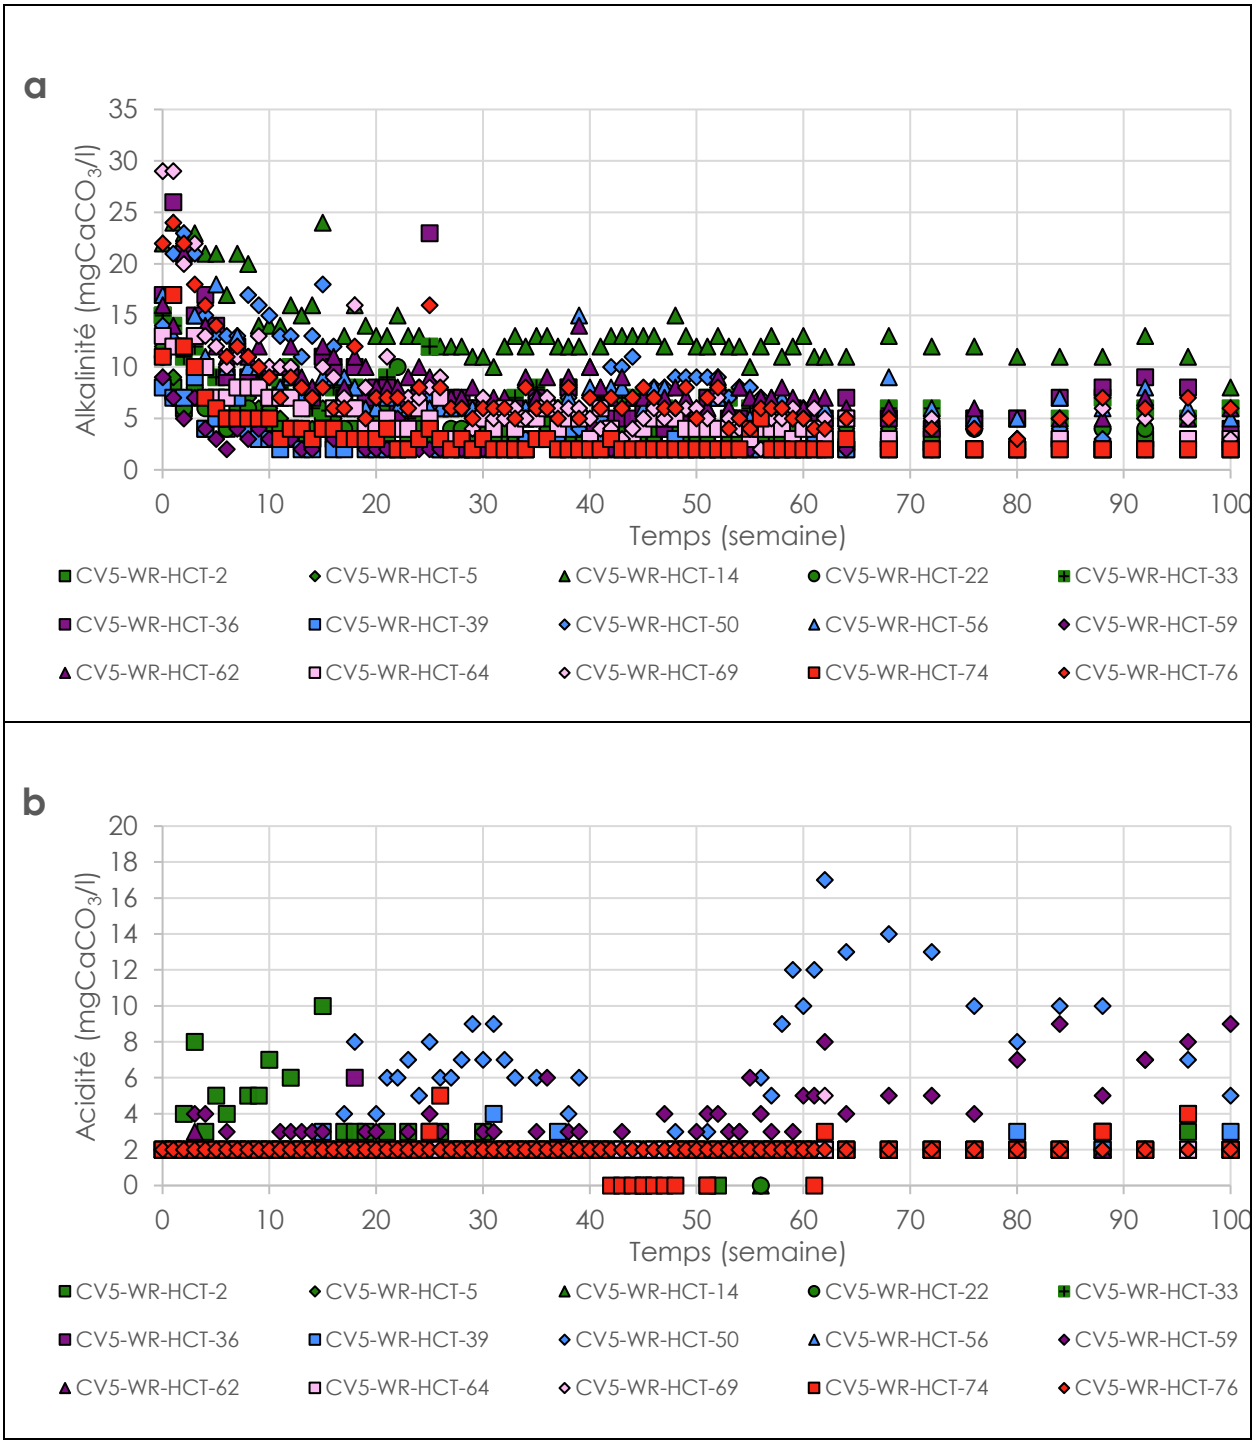

Figure 11. Tendances en matière d'alcalinité et d'acidité dans les essais en cellules humides

Les graphiques présentés dans la **Figure 12** illustrent le suivi des concentrations des produits de neutralisation et d'oxydation tout au long de l'expérience, à savoir le calcium (a) et le magnésium (b) d'une part, et le sulfate (c) d'autre part. Les tendances

de ces éléments étaient assez similaires d'un essai à l'autre et suivaient généralement une courbe descendante lente et régulière après un léger pic observé lors des premiers rinçages. Il convient de souligner que les résidus de DMS présentent des concentrations plus faibles pour tous ces éléments, ce qui suggère que les phénomènes d'oxydation et de neutralisation se produisent à un rythme plus lent dans ces matériaux.

a. Les concentrations en calcium présentent une variabilité initiale entre les HCT, avec des valeurs allant de 0,72 mg/L (CV5-WR-HCT-74) à 15,9 mg/L (CV5-WR-HCT-50). Au fil du temps, on observe une baisse générale, en particulier au cours des 20 premières semaines, car le calcium est libéré par la dissolution du carbonate due au tamponnage acide, soit par l'oxydation des minéraux sulfurés, soit par l'acidité inhérente à l'eau déionisée utilisée dans les HCT. À la semaine 100, le CV5-WR-HCT-50 (Métasédiments) garde des niveaux de calcium plus importants (~7-8 mg/L), reflétant des taux de neutralisation plus élevés, tandis que le CV5-WR-HCT-74 et le CV5-WR-HCT-64 (Pegmatite spodumène et Pegmatite stérile, respectivement) présentent des tendances à la baisse continue avec des valeurs comprises entre 0,2 et 0,8 mg/L. Les autres HCT se stabilisent généralement entre 2 et 5 mg/L, reflétant une dissolution continue mais diminuée des carbonates.

b. Les concentrations en magnésium suivent les mêmes tendances générales que celles du calcium, avec des valeurs comprises entre 5,73 mg/L et 0,05 mg/L, et semblent plus importantes dans les échantillons ultramafiques et plus faibles dans les résidus DMS.

c. Les concentrations en sulfate présentent une variabilité notable, allant de 2 mg/L dans plusieurs HCT à 53 mg/L dans le CV5-WR-HCT-50 (Métasédiments). Une baisse rapide est observée au cours des 20 premières semaines, en particulier pour le CV5-WR-HCT-50, qui passe de 53 mg/L à environ 10-15 mg/L, tandis que les autres HCT se stabilisent à des niveaux plus bas, généralement entre 2 et 10 mg/L. À la semaine 100, le CV5-WR-HCT-50 présente toujours les niveaux de sulfate les plus élevés (~19-21 mg/L), reflétant l'oxydation continue des minéraux sulfurés, tandis que le CV5-WR-HCT-2 (amphibolite) et le CV5-WR-HCT-59 (ultramafique) se stabilisent respectivement autour de 10 à 15 mg/L et 3 à 6 mg/L. La plupart des autres HCT, y compris CV5-WR-HCT-14, CV5-WR-HCT-22, CV5-WR-HCT-33, CV5-WR-HCT-64, CV5-WR-HCT-69, CV5-WR-HCT-74 et CV5-WR-HCT-76, maintiennent des concentrations de sulfate faibles (2 à 4 mg/L), ce qui indique une oxydation sulfureuse limitée.

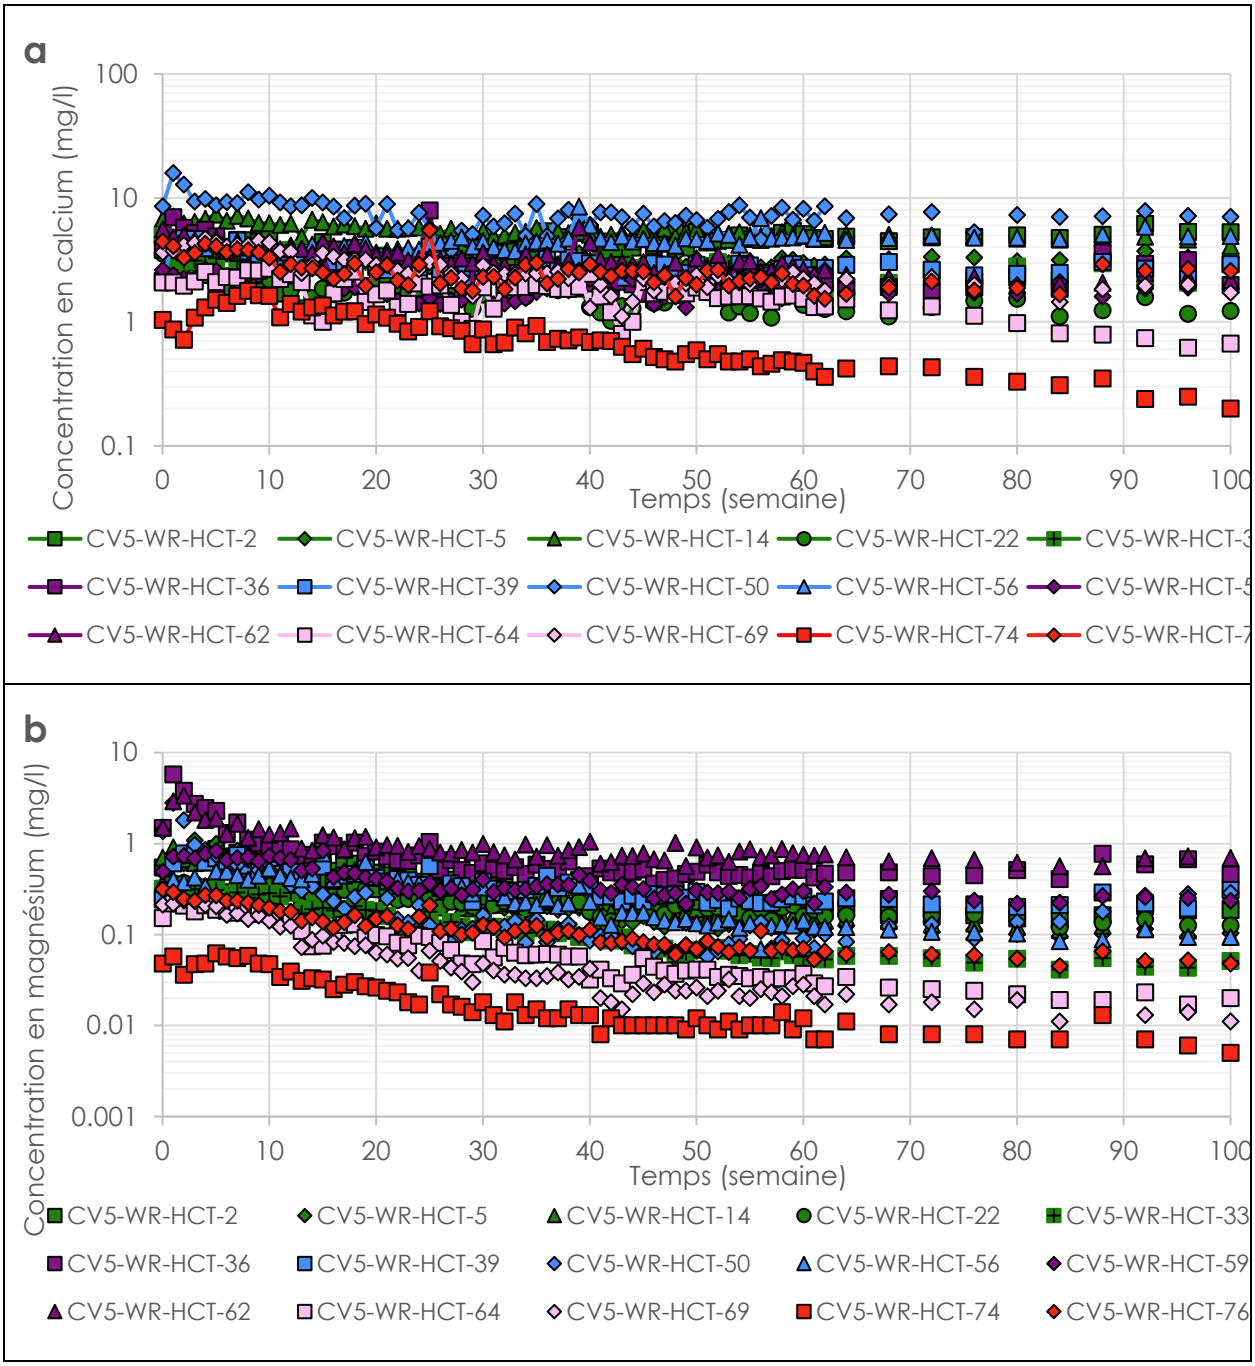

Figure 12. Tendances des produits d'oxydation et de neutralisation dans les essais en cellules humides (1 sur 2)

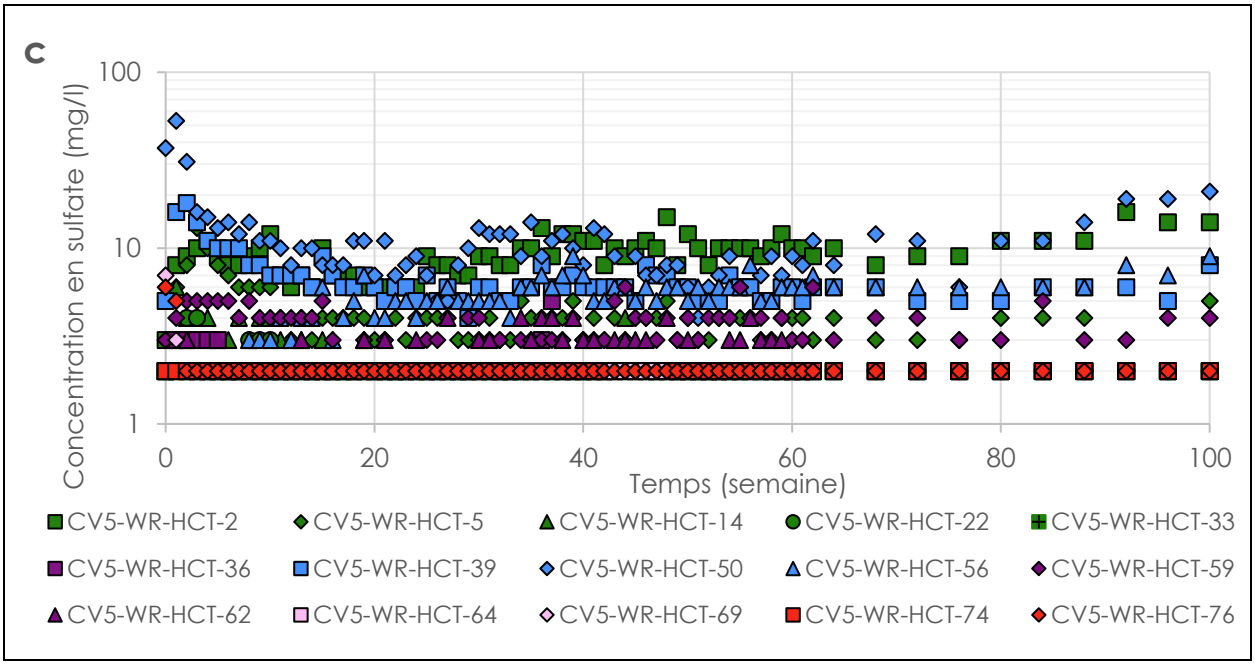

Figure 12. Tendances relatives aux produits d'oxydation et de neutralisation dans les essais en cellules humides (2 sur 2)

Les graphiques de la **Figure 13** présentent les résultats HCT du COPC qui ont été identifiés dans le cadre des essais de lixiviation.

a. Les concentrations d'aluminium commencent avec des valeurs initiales allant de 0,001 mg/L (CV5-WR-HCT-62) à 0,257 mg/L (CV5-WR-HCT-69), et diminuent rapidement au cours des 10 premières semaines dans tous les HCT. Au fil du temps, les concentrations se stabilisent à des niveaux faibles, généralement inférieurs à 0,05 mg/L pour la plupart des cellules. CV5-WR-HCT-14 (amphibolite) maintient des valeurs légèrement plus élevées (~0,08-0,1 mg/L), tandis que CV5-WR-HCT-36 (ultramafique) et CV5-WR-HCT-64 (pegmatite stérile) se stabilisent aux niveaux les plus bas, souvent inférieurs à 0,005 mg/L. CV5-WR-HCT-50 (métasédiments) et CV5-WR-HCT-69 (pegmatite stérile) présentent des fluctuations occasionnelles, mais restent inférieurs à 0,1 mg/L. La diminution de l'aluminium reflète une solubilité réduite à mesure que le pH se stabilise, limitant sa mobilité dans les cellules.

b. Les concentrations d'antimoine dans les échantillons de lixiviat variaient de 3,86 mg/L à la limite de détection (0,0009 mg/L). Les concentrations les plus élevées ont été observées dans les échantillons ultramafiques CV5-WR-HCT-36 (ultramafique) et CV5-WR-HCT-62 (ultramafique), avec des pics de 3,53 mg/L et 3,86 mg/L, respectivement, au cours des premières semaines. Les deux échantillons ultramafiques ont présenté des concentrations élevées constantes, CV5-WR-HCT-36 (ultramafique) dépassant 1,1 mg/L dans 47 occurrences et CV5-WR-HCT-62 (ultramafique) dans 52 occurrences au cours de la période de 100 semaines. Après les premiers rinçages, une tendance générale à la baisse a été observée pour ces échantillons, bien que les concentrations soient restées élevées pendant une période prolongée. L'échantillon de métasédiments CV5-WR-HCT-56 (métasédiments) a continué à présenter des concentrations égales ou proches de la limite de détection tout au long de l'essai. D'autres échantillons, tels que CV5-WR-HCT-5 (amphibolite) et CV5-WR-HCT-50 (métasédiments), ont présenté des concentrations élevées au début, mais celles-ci ont généralement diminué avec le temps, avec seulement quelques dépassements occasionnels de la limite de détection au cours des dernières semaines.

c. Les concentrations d'arsenic variaient entre 19,6 et 0,0024 mg/L dans tous les échantillons et toutes les chasses d'eau, affichant une tendance générale à la baisse depuis le début de l'essai. Dans les échantillons ultramafiques (CV5WR-HCT-36, CV5WR-HCT-59 et CV5WR-HCT-62), les concentrations étaient particulièrement élevées, atteignant 19,6 mg/L dans CV5WR-HCT-36 et 8,4 mg/L dans CV5WR-HCT-62 lors des premières chasses d'eau. Ces valeurs ont diminué de manière significative au cours des 20 premiers rinçages avant de se stabiliser progressivement entre 0,5 et 1,2 mg/L après la semaine 60. Les échantillons d'amphibolite présentaient des concentrations en arsenic beaucoup plus faibles que les stériles ultramafiques, avec une variabilité plus importante au début de l'essai, mais se stabilisant après la semaine 40 dans une fourchette d'environ 0,001 à 0,1 mg/L (par exemple, CV5WR-HCT-2). Les échantillons de stériles de pegmatite (CV5WR-HCT-64 et CV5WR-HCT-69) et l'échantillon de minerai de spodumène de pegmatite (CV5WRHCT-74) ont également présenté des concentrations élevées lors des premiers lavages (0,2 à 0,5 mg/L), qui ont rapidement diminué au cours des semaines

suivantes, pour atteindre de manière constante moins de 0,01 mg/L après la semaine 30 et rester stables par la suite.

d. Les concentrations de béryllium restent constamment faibles dans tous les HCT, avec des valeurs initiales généralement égales ou proches de la limite de détection de 0,000007 mg/L. CV5-WR-HCT-69 (pegmatite stérile) commence avec les concentrations les plus élevées, atteignant un pic de 0,000437 mg/L à la semaine 0, mais diminue rapidement pour se stabiliser en dessous de 0,0001 mg/L à la semaine 20. CV5-WR-HCT-64 (Pegmatite stérile) et CV5-WR-HCT-50 (Métasédiments) présentent des fluctuations mineures occasionnelles, CV5-WR-HCT-64 atteignant un maximum de 0,000365 mg/L à la semaine 68 et CV5-WR-HCT-50 atteignant un pic de 0,00012 mg/L à la semaine 100. Tous les autres HCT maintiennent des concentrations proches ou inférieures à la limite de détection (0,000007 mg/l) tout au long de la période de surveillance, ce qui indique une mobilité minimale du béryllium à partir de ces matériaux.

e. Les concentrations de cadmium restent faibles dans toutes les cellules HCT, avec des valeurs initiales généralement égales ou proches de la limite de détection de 0,000003 mg/L. La cellule CV5-WR-HCT-50 (métasédiments) présente des concentrations légèrement plus élevées que les autres cellules, avec un pic à 0,000132 mg/l à la semaine 100, tandis que les cellules CV5-WR-HCT-39 (Métasédiments) et CV5-WR-HCT-69 (Pegmatite stérile) présentent des fluctuations mineures occasionnelles, mais restent inférieures à 0,00006 mg/l. Tous les autres HCT maintiennent des concentrations proches ou inférieures à la limite de détection tout au long de la période de surveillance, ce qui indique une libération ou une mobilité minimale du cadmium dans ces cellules.

f. Les concentrations de cuivre sont restées très faibles tout au long des essais, fluctuant généralement près de la limite de détection analytique. Les valeurs ont montré une variabilité mineure sans tendance à la hausse soutenue. Il convient de noter que la limite de détection est passée de 0,0002 mg/L (jusqu'à la semaine 38) à 0,001 mg/L par la suite, ce qui explique en partie la stabilisation apparente des résultats dans les dernières phases.

g. Les concentrations en fer étaient initialement proches de la limite de détection (0,007 mg/L) dans la plupart des HCT, avec plusieurs augmentations transitoires observées entre les semaines 10 et 30, atteignant jusqu'à 0,15 mg/L. Après la semaine 40, les concentrations se sont généralement stabilisées près de la limite de détection, bien que l'échantillon de stériles métasédimentaires CV5-WR-HCT-50 ait montré une augmentation soutenue, dépassant 0,7 mg/L à la semaine 100, tandis que l'échantillon de stériles ultramafiques CV5-WR-HCT-59 a maintenu des pics récurrents modérés allant jusqu'à 0,03 mg/L. Dans l'ensemble, le comportement du fer a été caractérisé par des événements de mobilisation de courte durée suivis d'une stabilisation, seuls quelques cas isolés présentant des élévations persistantes.

h. Les concentrations de lithium dans les échantillons de lixiviat variaient entre 0,918 mg/L et la limite de détection (0,0002 mg/L), et toutes les lithologies ont suivi une tendance à la baisse au cours de la période de 100 semaines. Les échantillons de pegmatite spodumène (CV5-WR-HCT-74, CV5-WR-HCT-76), ainsi que l'échantillon de métasédiment CV5-WR-HCT-50, ont présenté les concentrations les plus élevées, en particulier au cours des premières semaines. Les échantillons de stériles de pegmatite (CV5-WR-HCT-64, CV5-WR-HCT-69) ont également présenté des concentrations élevées au début de l'essai, mais ont semblé diminuer plus rapidement que les autres lithologies. Les échantillons ultramafiques (CV5-WR-HCT-36, CV5-WR-HCT-62) sont restés parmi les plus faibles tout au long de l'essai.

i. Les concentrations en nickel étaient généralement faibles dans la plupart des HCT, avec des valeurs proches de la limite de détection (0,0001 mg/l) dans les échantillons d'amphibolite, de pegmatite stérile et de pegmatite spodumène. En revanche, les échantillons de stériles ultramafiques CV5-WR-HCT-36 et CV5-WR-HCT-62 ont présenté des concentrations élevées au début des essais, suivies d'une diminution progressive et d'une relative stabilisation, ce qui suggère un lavage initial des phases nickelifères facilement solubles. Les échantillons ultramafiques CV5-WR-HCT-59 et métasédimentaires CV5-WR-HCT-50 ont affiché une tendance différente, avec des concentrations augmentant régulièrement pour atteindre des valeurs proches de 0,1 mg/L à la semaine 100.

j. Les concentrations d'uranium variaient entre 0,000002 mg/L et 0,101 mg/L au cours de la période d'essai de 100 semaines. La plupart des échantillons, y compris les lithologies amphibolite, ultramafique, métasédimentaire et pegmatite, présentaient des concentrations d'uranium généralement égales ou proches de la limite de détection, avec des pics occasionnels. Il convient de noter que les échantillons CV5-WR-HCT-69 (pegmatite stérile) et CV5-WR-HCT-74 (pegmatite spodumène) ont présenté des concentrations plus élevées, avec des pics respectifs de 0,101 mg/L et 0,0539 mg/L au cours des premières semaines. CV5-WR-HCT-50 (métasédiment) et CV5-DMS-HCT-83 (métasédiment) ont également affiché des concentrations élevées, avec des pics de 0,0558 mg/L et 0,0166 mg/L, respectivement. Malgré ces augmentations occasionnelles, la lixiviation de l'uranium est restée relativement faible dans tous les échantillons, les concentrations revenant généralement à des niveaux proches de ceux du fond après les premières semaines.

k. Les concentrations de zinc sont restées très faibles dans presque tous les HCT, fluctuant généralement à la limite de détection (0,002 mg/L) ou juste au-dessus pendant toute la durée de l'essai. Ces variations reflètent probablement le bruit associé aux mesures proches de la limite de détection. L'échantillon de stériles Métasédiment CV5-WR-HCT-50 a été le seul à présenter une augmentation claire et soutenue, avec des concentrations augmentant régulièrement après la semaine 60 et dépassant 0,3 mg/L à la semaine 100.

3.3.2 Essai sur colonne

Figure 14 affiche la variation cinétique des paramètres physicochimiques des essais sur colonne, à savoir le pH (a) et la conductivité électrique (b).

a. Les valeurs de pH pour tous les essais en colonne — Flottants (CV5-CL-1), Middlings (CV5-CL-2), Magnétiques (CV5-CL-3), Bypass (CV5-CL-4) et Composite maître (CV5-CL-5) — sont restées neutres à légèrement alcalines pendant la période de 20 semaines. Les valeurs initiales variaient entre 7,27 et 9,34, avec une tendance générale à la baisse dans toutes les colonnes. Les flottants et les middlings ont commencé avec les niveaux de pH les plus élevés (9,34 et 9,2) et ont progressivement diminué pour atteindre environ 7,5-8,0. Les résidus magnétiques ont commencé avec le pH initial le plus bas (7,27) et ont continué à baisser jusqu'à 6,93, tandis que les résidus de dérivation et les résidus composites ont affiché des baisses modérées, terminant respectivement à près de 7,5 et 7. Dans l'ensemble, les résultats reflètent une évolution progressive vers la neutralité pour tous les types de résidus.

b. Les valeurs de conductivité électrique dans les essais en colonne ont diminué de manière significative au cours de la période de 20 semaines pour tous les types de résidus. Les flottants (CV5-CL-1) ont commencé à 508 µS/cm et ont diminué à 30 µS/cm, tandis que les middlings (CV5-CL-2) ont chuté de 173 µS/cm à 34 µS/cm. Les résidus magnétiques (CV5-CL-3) ont affiché une réduction progressive de 223 µS/cm à 39 µS/cm. Les résidus de dérivation (CV5-CL-4) ont commencé avec la conductivité initiale la plus élevée, à 3490 µS/cm, mais ont connu une baisse substantielle, pour finir à 82 µS/cm. Le Master Composite (CV5-CL-5) a suivi une tendance à la baisse similaire, passant de 401 µS/cm à 46 µS/cm. Dans l'ensemble, les résultats indiquent une réduction constante de la conductivité dans toutes les colonnes, reflétant une diminution des taux de lixiviation au fil du temps, le Bypass présentant les valeurs initiales les plus significatives et la baisse la plus importante par la suite.

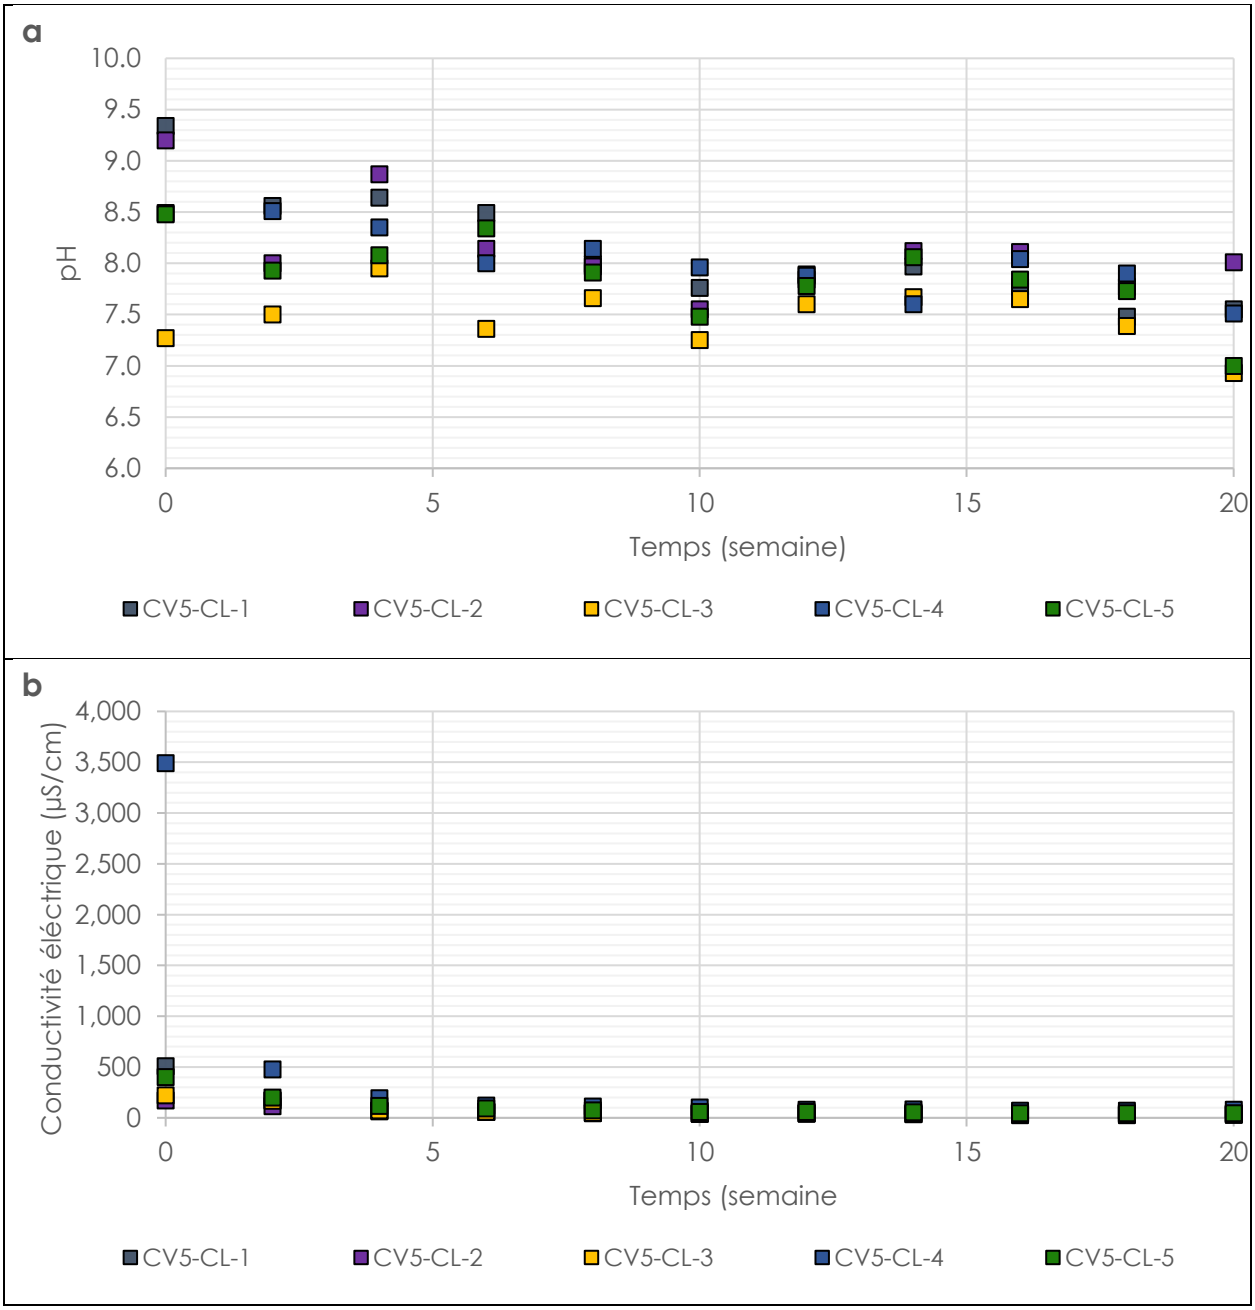

Figure 14. Évolution de la conductivité et du pH dans les essais en colonne

Les graphiques affichés dans **Figure 15** présenter les mesures d'alcalinité (a) et d'acidité (b) surveillées tout au long des 20 semaines d'essais sur colonne.

a. Les valeurs d'alcalinité dans les essais en colonne ont montré une tendance générale à la baisse sur la période de 20 semaines pour tous les types de résidus. Les flottants (CV5-CL-1) ont commencé à 75 mgCaCO3/ l et ont progressivement diminué pour atteindre 14 mgCaCO3/l, tandis que les middlings (CV5-CL-2) ont diminué de 59 mg/L à 20 mgCaCO3/l, avec quelques fluctuations au cours des dernières semaines. Le groupe Magnetics (CV5-CL-3) a présenté une alcalinité relativement faible et stable, comprise entre 11 mg/L et 26 mgCaCO3/l, pour finir à 13 mgCaCO3/l. Le Bypass (CV5-CL-4) présentait l'alcalinité initiale la plus élevée, à 448 mg/L, qui a considérablement diminué pour atteindre 37 mgCaCO3/l à la semaine 20. Le composite maître (CV5-CL-5) a suivi une tendance à la baisse similaire, passant de 53 mgCaCO3/l à 23 mgCaCO3/l. Dans l'ensemble, l'alcalinité a diminué dans toutes les colonnes, le by-pass présentant les valeurs initiales les plus prononcées et la réduction la plus importante.

b. Les valeurs d'acidité pour tous les types de résidus sont restées égales ou inférieures à la limite de détection de 2 mg$CaCO_3$/l tout au long de la période d'essai de 20 semaines, ce qui indique qu'aucune génération d'acide significative ne s'est produite dans aucune des colonnes. Cette cohérence confirme l'absence de potentiel de génération d'acide de ce matériau pendant cette période.

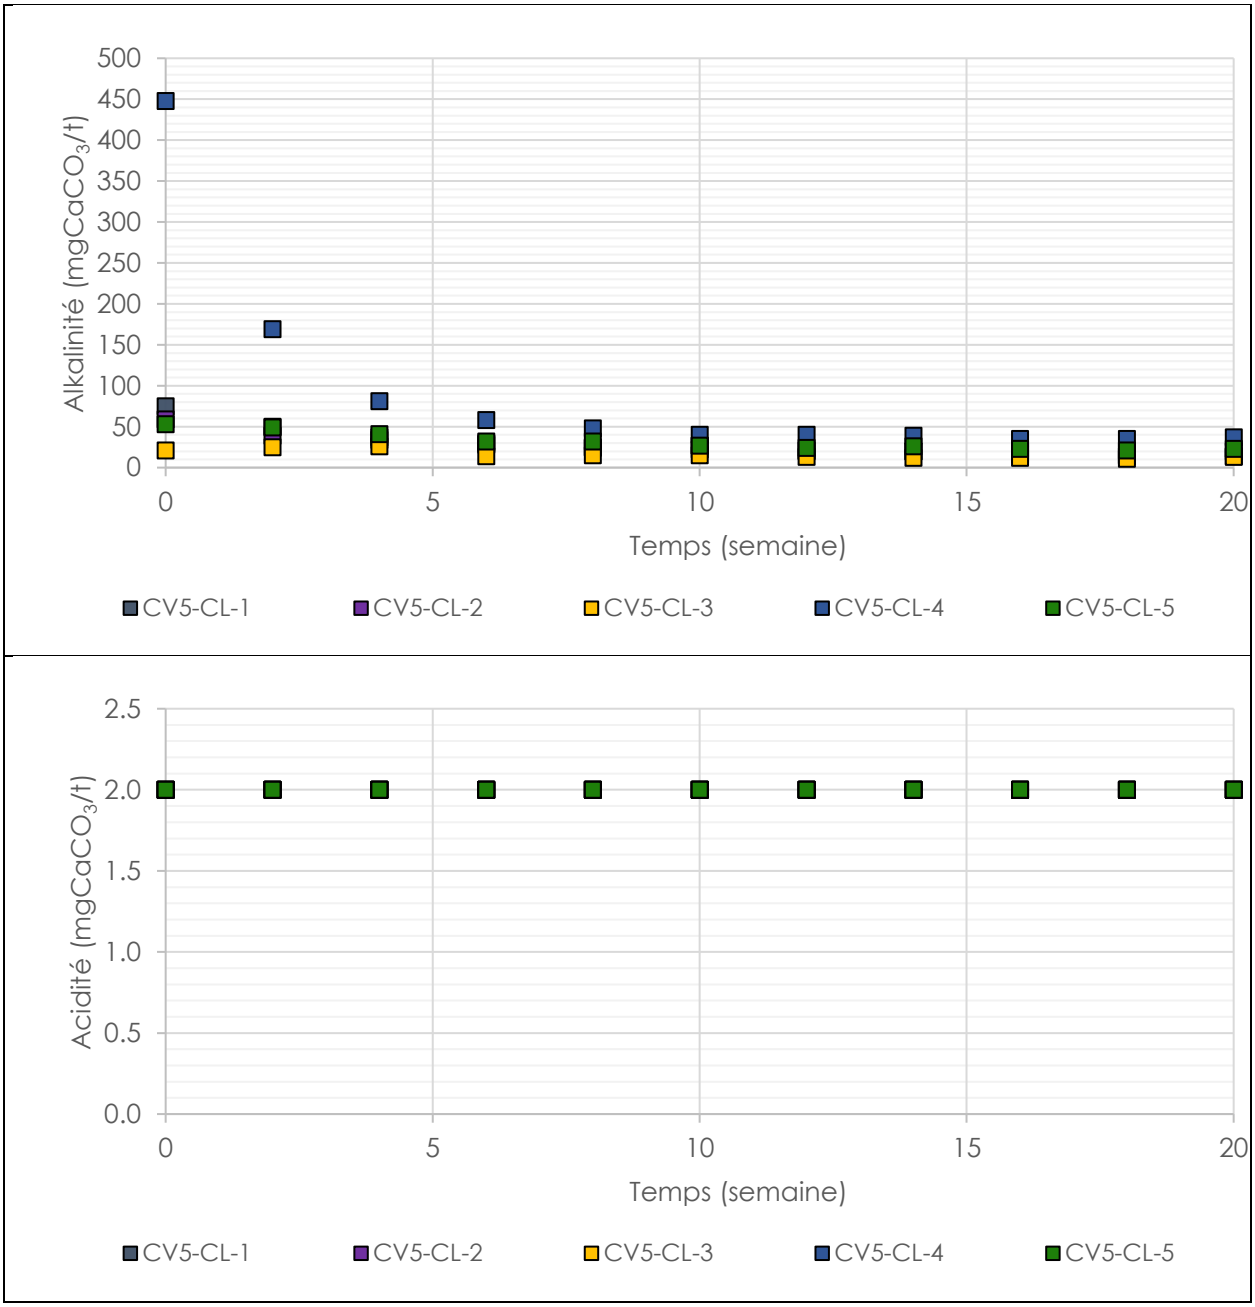

Figure 15. Évolution de l'alcalinité et de l'acidité dans les essais en colonne

Les graphiques de la **Figure 16** présentent les résultats des essais sur colonne des COPC identifiés dans le cadre des essais de lixiviation. Ceux-ci comprennent : l'aluminium (a), l'antimoine (b), l'arsenic (c), le cuivre (d), le lithium l et l'uranium (f).

a. Les concentrations d'aluminium dans les essais en colonne ont varié selon les types de résidus au cours de la période de 20 semaines. Les flottants (CV5-CL-1) ont montré une diminution progressive de 0,237 mg/l à 0,198 mg/l, maintenant des concentrations relativement stables après la baisse initiale. Les middlings (CV5-CL-2) ont commencé à 0,3 mg/l et ont diminué jusqu'à 0,168 mg/l, reflétant une réduction constante au fil du temps. Les résidus magnétiques (CV5-CL-3) ont constamment présenté les concentrations d'aluminium les plus faibles, commençant à 0,075 mg/l et se stabilisant autour de 0,04 mg/l. Les résidus de dérivation (CV5-CL-4) présentaient initialement de faibles concentrations à 0,024 mg/l, mais ont augmenté pour atteindre environ 0,142 mg/l, indiquant une légère tendance à la hausse. Le Master Composite (CV5-CL-5) a affiché une baisse de 0,206 mg/l à 0,114 mg/l, avec des fluctuations mineures. Dans l'ensemble, les concentrations d'aluminium ont eu tendance à se stabiliser à des niveaux plus bas à la fin de la période d'essai, Magnetics affichant systématiquement les valeurs les plus faibles.

b. Les concentrations d'antimoine dans les essais en colonne ont affiché des tendances variables selon les types de résidus au cours de la période de 20 semaines. Les flottants (CV5-CL-1) ont commencé à 0,0507 mg/l, ont atteint un pic de 0,302 mg/l à la deuxième semaine, puis ont diminué régulièrement pour atteindre 0,0607 mg/l. Les middlings (CV5-CL-2) ont suivi une tendance similaire, commençant à 0,0745 mg/l, atteignant un pic de 0,35 mg/l à la deuxième semaine, puis diminuant progressivement jusqu'à 0,12 mg/l. Les particules magnétiques (CV5-CL-3) ont affiché une augmentation constante, passant de 0,0845 mg/l à un pic de 0,778 mg/l à la semaine 6, suivi d'une légère baisse à 0,607 mg/l. Le Bypass (CV5-CL-4) a présenté la concentration initiale la plus élevée, à 1,68 mg/l, avec un pic à 5,47 mg/l à la deuxième semaine, avant de diminuer progressivement jusqu'à 0,247 mg/l. Le composite principal (CV5-CL-5) a commencé à 0,12 mg/l, a atteint un pic de 0,999 mg/l à la deuxième semaine, puis a diminué pour atteindre 0,226 mg/l. Dans l'ensemble, les niveaux d'antimoine ont généralement atteint leur pic au début de la période d'essai, puis ont diminué, Magnetics maintenant des concentrations relativement stables et Bypass affichant le pic initial le plus important.

c. Les concentrations d'arsenic dans les essais en colonne ont montré des tendances distinctes selon les types de résidus au cours de la période de 20 semaines. Pour les résidus flottants (CV5-CL-1), les niveaux d'arsenic ont commencé à 0,496 mg/l et ont diminué régulièrement jusqu'à 0,0864 mg/l, montrant une réduction constante au fil du temps. Les middlings (CV5-CL-2) ont commencé à 0,404 mg/l, ont atteint un pic de 1,51 mg/l à la deuxième semaine, puis ont progressivement diminué pour atteindre 0,458 mg/l. Les résidus magnétiques (CV5-CL-3) ont affiché les concentrations initiales les plus élevées, commençant à 0,561 mg/l et atteignant un pic de 5,08 mg/l à la quatrième semaine, avant de diminuer progressivement jusqu'à 2,6 mg/l. Le Bypass (CV5-CL-4) présentait les niveaux d'arsenic les plus élevés, commençant à 4,47 mg/l, atteignant un pic de 17,6 mg/l à la deuxième semaine, puis diminuant jusqu'à 1,67 mg/l à la vingtième

semaine. Le composite principal (CV5-CL-5) a présenté une tendance similaire, commençant à 0,548 mg/l, atteignant un pic de 4,47 mg/l à la deuxième semaine, puis diminuant jusqu'à 1,24 mg/l. Dans l'ensemble, les concentrations d'arsenic ont eu tendance à diminuer après les pics initiaux, le Bypass et les résidus magnétiques présentant les niveaux les plus élevés tout au long de la période d'essai.

d. Les concentrations de cuivre dans les essais en colonne sont restées faibles pour tous les types de résidus pendant toute la période de 20 semaines. Les résidus flottants (CV5-CL-1) ont commencé à 0,004 mg/l et ont rapidement chuté à 0,001 mg/l dès la deuxième semaine, maintenant ce niveau jusqu'à la fin de la période d'essai. Les middlings (CV5-CL-2), les magnétiques (CV5-CL-3) et le composite maître (CV5-CL-5) ont tous présenté des concentrations de cuivre stables, égales ou proches de la limite de détection de 0,001 mg/l pendant toute la durée de l'essai. Le Bypass (CV5-CL-4) a initialement présenté une concentration légèrement supérieure de 0,028 mg/l, mais celle-ci a rapidement diminué pour atteindre 0,001 mg/l à la quatrième semaine et est restée constante par la suite. Dans l'ensemble, la lixiviation du cuivre a été minime dans toutes les colonnes, les concentrations se stabilisant à 0,001 mg/l ou moins après les premières semaines.

e. Les concentrations de lithium dans les essais en colonne ont montré une baisse rapide et régulière pour tous les types de résidus miniers au cours de la période de 20 semaines. Les flottants (CV5-CL-1) ont commencé à 0,82 mg/l et ont fortement diminué pour atteindre 0,0174 mg/l à la semaine 20. Les middlings (CV5-CL-2) ont suivi une tendance similaire, commençant à 0,897 mg/l et diminuant jusqu'à 0,038 mg/l. Les résidus magnétiques (CV5-CL-3) ont affiché une tendance comparable, passant de 0,521 mg/l à 0,0335 mg/l. Les résidus de dérivation (CV5-CL-4) présentaient la concentration initiale la plus élevée, à 35,1 mg/l, qui a considérablement diminué pour atteindre 0,246 mg/l à la semaine 20. Le composite maître (CV5-CL-5) a également affiché une baisse constante, passant de 1,84 mg/l à 0,0887 mg/l. Dans l'ensemble, les concentrations de lithium dans toutes les colonnes ont suivi une tendance à la baisse parallèle, le Bypass présentant les concentrations initiales les plus élevées et la réduction la plus prononcée au fil du temps.

f. Les concentrations d'uranium dans les essais en colonne ont suivi des tendances à la baisse similaires pour tous les types de résidus au cours de la période de 20 semaines, mais à des niveaux d'amplitude différents. Les flottants (CV5-CL-1) ont commencé à 0,056 mg/l, ont atteint un pic de 1,27 mg/l à la deuxième semaine, puis ont progressivement diminué pour atteindre 0,131 mg/l. Les middlings (CV5-CL-2) ont commencé à 0,00115 mg/l, ont atteint un maximum de 0,383 mg/l à la quatrième semaine, puis ont diminué pour atteindre 0,136 mg/l. Les résidus magnétiques (CV5-CL-3) ont présenté des concentrations initiales plus faibles, commençant à 0,0165 mg/l, atteignant un pic de 0,109 mg/l à la deuxième semaine, puis diminuant jusqu'à 0,0286 mg/l. Le Bypass (CV5-CL-4) a présenté les concentrations les plus élevées, commençant à 0,0996 mg/l, atteignant un pic de 0,946 mg/l à la deuxième semaine, puis se stabilisant autour de 0,417 mg/l. Le composite principal (CV5-CL-5) a commencé à 0,00644 mg/l, a atteint un pic de 0,465 mg/l à la quatrième semaine, puis a diminué pour atteindre 0,259

mg/l. Dans l'ensemble, toutes les colonnes ont affiché des tendances parallèles à la baisse après les pics initiaux, le Bypass conservant les concentrations d'uranium les plus élevées tout au long de la période d'essai.

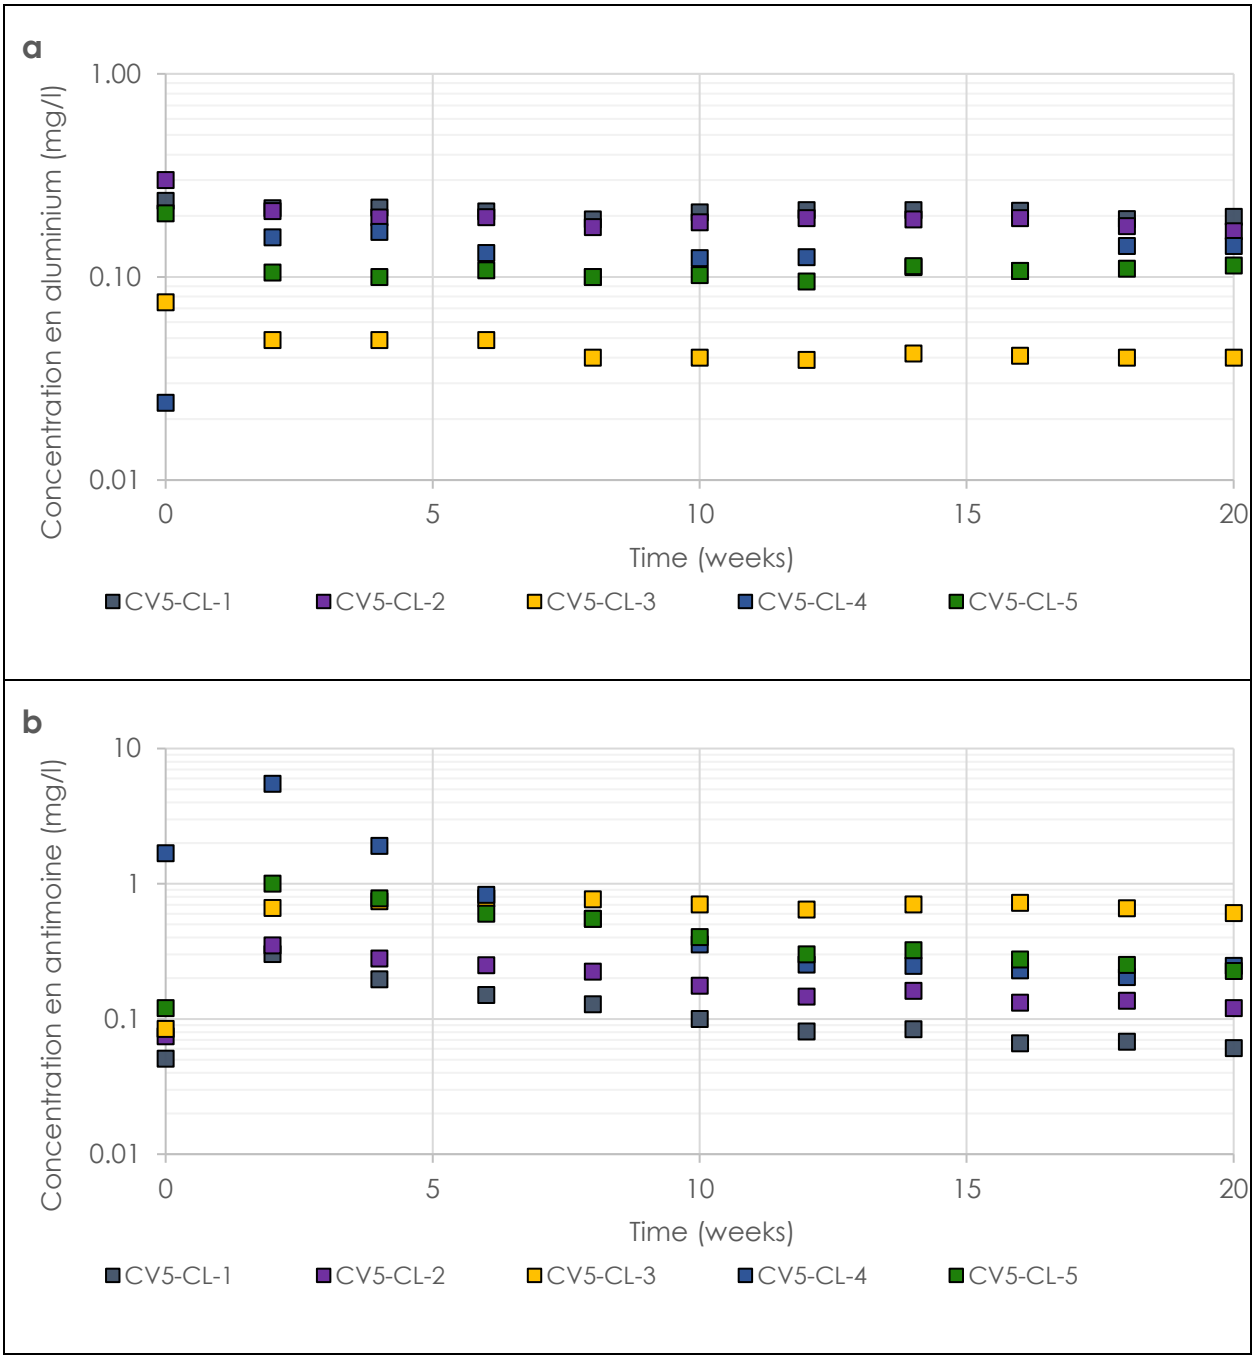

Figure 16. Représentation graphique de la concentration des COPC dans les essais en colonne (1 sur 3)

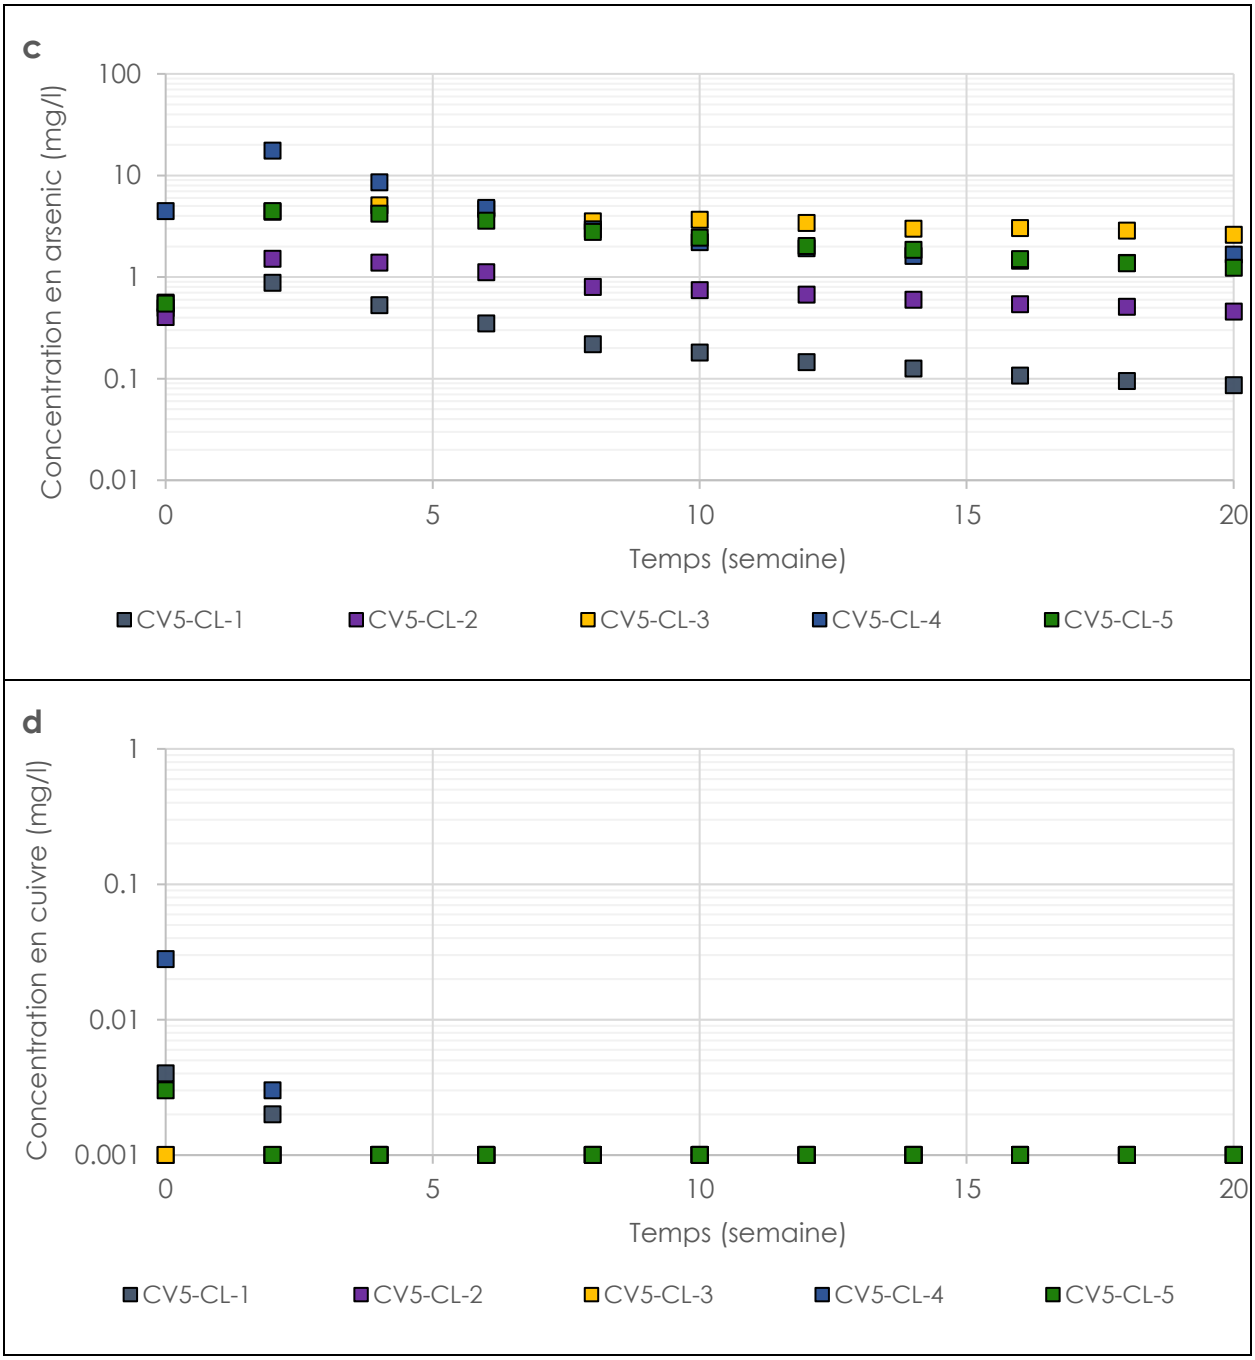

Figure 17. Représentation graphique de la concentration des COPC dans les essais en colonne (2 sur 3)

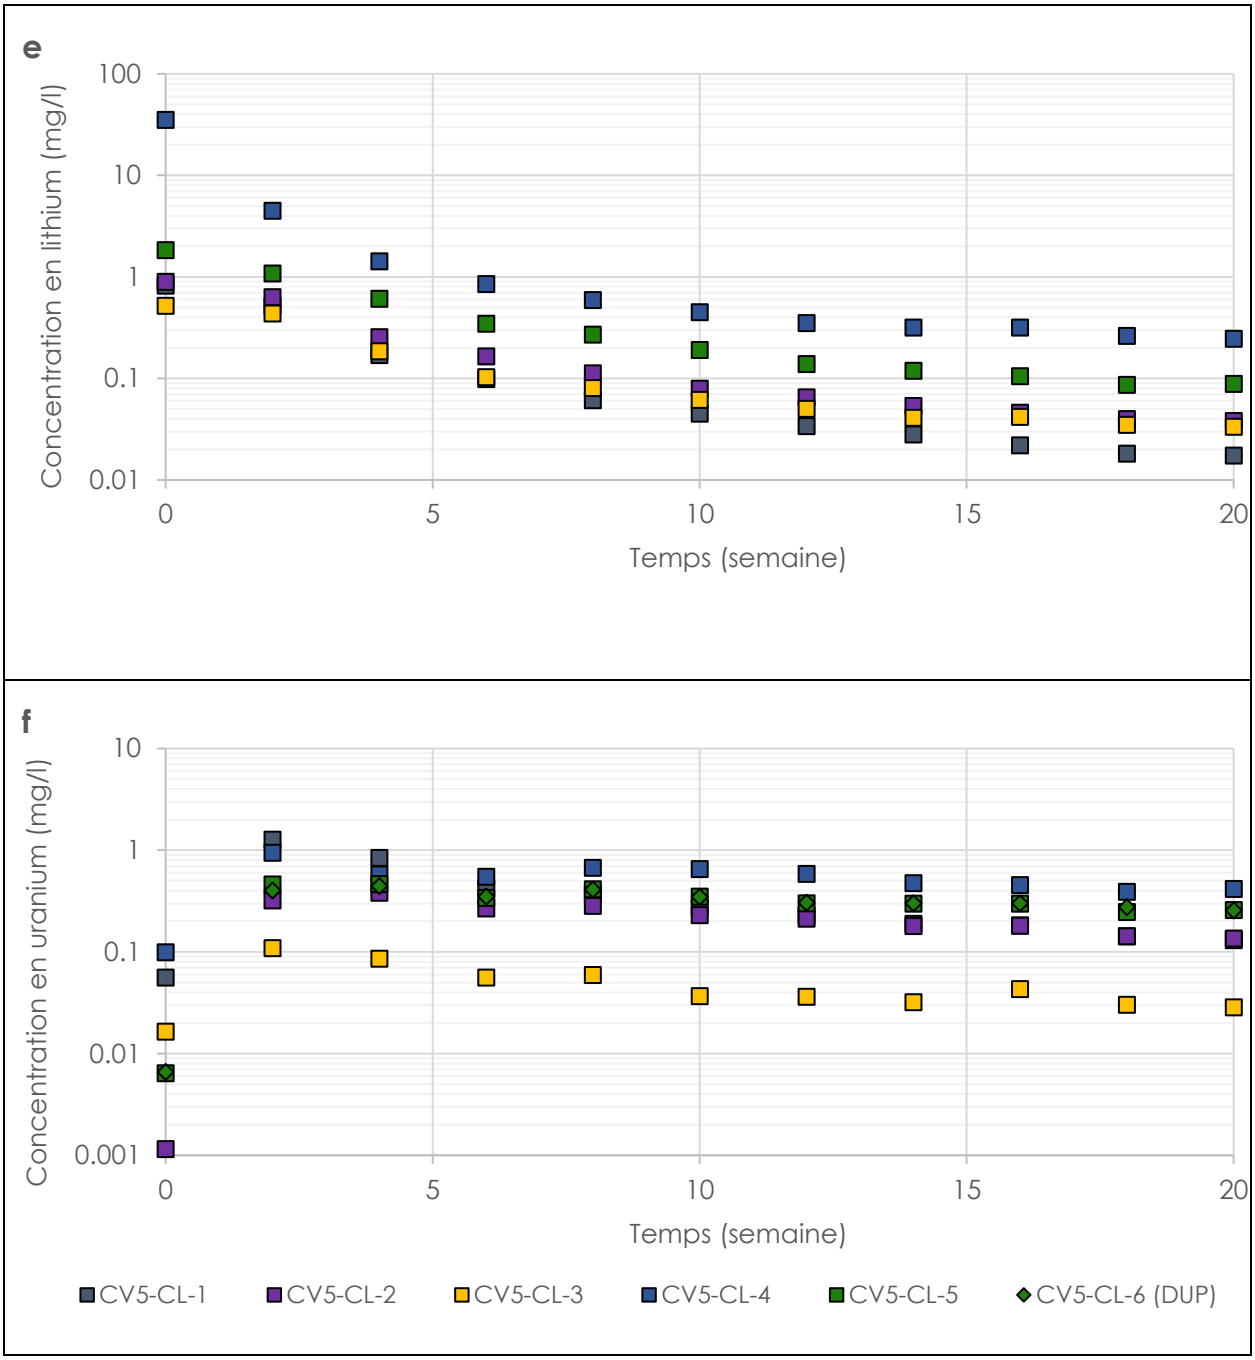

Figure 16. Représentation graphique de la concentration des COPC dans les essais en colonne (3 sur 3)

3.3.3 Résumé et interprétation

Des essais cinétiques en double ont été réalisés afin d'évaluer la reproductibilité et la fiabilité des essais HCT effectués sur des échantillons de stériles et de minerai (CV5-WR-HCT-5 (DUP)), ainsi que des essais en colonne effectués sur des résidus (CV5-CL-6). Dans les essais HCT en double, 69 % des paramètres testés ont présenté un écart relatif en pourcentage (RPD) inférieur à 20 % (indiquant une bonne reproductibilité), 27 % se situaient entre 20 % et 50 % (acceptable) et 4,4 % se situaient entre 50 % et 100 % (reflétant une plus grande incertitude). Pour les duplicatas des essais en colonne, 95 % des paramètres présentaient un RPD inférieur à 20 % et 5,3 % se situaient entre 20 % et 50 %. Dans l'ensemble, les essais cinétiques ont démontré une bonne reproductibilité. La variabilité légèrement plus élevée observée dans les duplicatas HCT est attribuée à la distribution granulométrique plus grossière et plus hétérogène des stériles par rapport aux résidus, ainsi qu'à la masse d'échantillon plus faible utilisée dans les HCT (environ 1 kg sec) par rapport aux essais sur colonne (8-9,5 kg sec), ce qui amplifie l'influence de l'hétérogénéité de l'échantillonnage.

Après 100 semaines, les essais HCT n'ont pas révélé de comportement acidogène net clair, bien qu'une diminution générale du pH ait été observée. Certains HCT ont affiché des valeurs légèrement inférieures à 6 vers la fin de la période d'essai (par exemple, CV5-WR-HCT-59 et CV5-WR-HCT-39), et des augmentations de certains métaux de base ont été notées, notamment le cadmium, le fer, le manganèse, le nickel et le zinc dans CV5-WR-HCT-50, ou le nickel dans CV5-WR-HCT-59. Il convient de souligner que la procédure HCT tend à favoriser le développement de conditions légèrement acides, quels que soient les résultats ABA d'un matériau, en raison du rapport liquide/solide élevé, de l'utilisation d'eau déionisée (pH 5,5-6) et du débit de rinçage rapide.

Parmi les COPC identifiés dans le cadre des essais de lixiviation (**Tableau 20**), l'arsenic s'est révélé être le plus susceptible de dépasser les critères CVAA et MDMER / D019, avec respectivement 14,1 % et 25,3 % de dépassements hebdomadaires, suivi par l'antimoine, avec 9,3 % de dépassements hebdomadaires du critère CVAA. À cet égard, il convient de souligner que l'arsenic et l'antimoine apparaissaient tous deux élevés dans les échantillons ultramafiques, qui représentaient respectivement plus de 98 % et 90 % des dépassements des critères CVAA pour l'antimoine et l'arsenic, bien que certains dépassements pour l'arsenic aient également été identifiés dans les amphibolites et les stériles de pegmatite, ainsi que dans les HCT de spodumène (minerai) de pegmatite.

Quelques dépassements ont également été observés pour certains métaux communs, en particulier dans les échantillons de métasédiments, notamment CV5-WR-HCT-50 qui a enregistré des dépassements pour le cadmium, le cuivre, le nickel et le zinc, bien que les HCT ultramafiques aient présenté quelques dépassements pour le nickel selon le critère CVAA, et que les HCT de pegmatite stérile et de pegmatite spodumène (minerai) aient présenté quelques dépassements pour le cuivre.

En ce qui concerne le cuivre, il convient toutefois de souligner que le critère CVAA (0,0016 mg/l) est inférieur à un ordre de grandeur au-dessus de la limite de détection (0,0002 mg/l jusqu'à la semaine 38 et 0,001 mg/l de la semaine 39 à la semaine 100), et que la limite de quantification de la méthode pourrait avoir influencé le nombre de dépassements enregistrés. Toutefois, étant

donné que la solubilité du cuivre est contrôlée par le pH, ce métal pourrait devenir une préoccupation plus importante si des conditions acides associées à l'oxydation des minéraux sulfurés apparaissaient.

Enfin, quelques dépassements de la teneur en uranium ont également été signalés dans les HCT de stériles pegmatitiques et de spodumène pegmatitique (minerai), notamment au début des essais sur colonne de résidus (**Tableau 21**) indiquent que l'arsenic a dépassé ses critères de criblage dans tous les types de matériaux : 4 dépassements dans les flottants (CV5-CL-1), 11 dans les middlings (CV5-CL-2), 11 dans les magnétiques (CV5-CL-3), 11 dans les bypass (CV5-CL-4) et 11 dans le composite maître (CV5-CL-5). Les dépassements pour l'antimoine étaient les plus prononcés dans les minéraux magnétiques (CV5-CL-3, 10), les minéraux de dérivation (CV5-CL-4, 6) et le composite maître (CV5-CL-5, 6), tandis que l'uranium ne dépassait ses critères que dans l'échantillon de dérivation (CV5-CL-4, 2). En comparaison, le cuivre, le nickel, le lithium et le zinc ont présenté peu de dépassements, avec des occurrences isolées telles que le cuivre dans les middlings (CV5-CL-2, 1), le nickel dans le Bypass (CV5-CL-4, 3) et le composite maître (CV5-CL-5, 2), le lithium dans les flottants (CV5-CL-1, 2) et le Bypass (CV5-CL-4, 2), et le zinc dans les flottants (CV5-CL-1, 4) et le Bypass (CV5-CL-4, 10). Ces résultats indiquent que l'arsenic, l'antimoine et l'uranium sont les principaux constituants potentiellement préoccupants dans les résidus testés.

3.4 Résultats de la modélisation géochimique

Une modélisation géochimique a été réalisée afin d'évaluer les risques liés au potentiel de lixiviation de l'antimoine, de l'arsenic et du lithium présents dans les stériles et les résidus miniers du site Stockpile-002, et de soutenir les mesures de gestion des stériles visant à prévenir les risques de lixiviation de l'arsenic sur le site Stockpile_001.

Les résultats des simulations Monte Carlo à 1 000 itérations réalisées pour prédire les concentrations d'arsenic dans les eaux de percolation des stériles à la base des stockages 001 et 002 sont résumés à l'**Annexe E**, avec les résultats du modèle déterministe des résidus du Stockpile-002.

3.4.1 Charge en arsenic des stériles

Figure 18 présente les distributions des taux de lixiviation en spécifique des matériaux stériles (par kilogramme de matériel) avant et après la ségrégation. Les résultats des 1 000 itérations sont distribués symétriquement, la moyenne correspondant étroitement à la médiane, ce qui correspond à une distribution quasi normale des résultats simulés. La ségrégation devrait permettre d'obtenir un taux de lixiviation global de l'arsenic de $1{,}92\times10^{-5}$ mg/kg/semaine en moyenne pour les matériaux destinés au Stockpile-001, soit environ dix fois moins que pour les matériaux non séparés ($2{,}55\times10^{-4}$ mg/kg/semaine). Le sous-produit lixiviable issu de la ségrégation placé dans le Stockpile-002 présenterait un taux moyen de $8{,}73\times10^{-4}$ mg/kg/semaine, soit 3,4 fois plus élevé que le matériau d'origine et 45 fois plus élevé que la fraction non lixiviable. Il convient toutefois de noter que le Stockpile-002 devrait comprendre environ 53 % de matériaux lixiviables et 47 % de matériaux non lixiviables en arsenic.

Ces rapports de taux de lixiviation devraient être indépendants des variations des facteurs d'échelle et autres paramètres d'étalonnage, car ces ajustements sont appliqués uniformément à tous les types de matériaux et préservent donc les différences relatives.

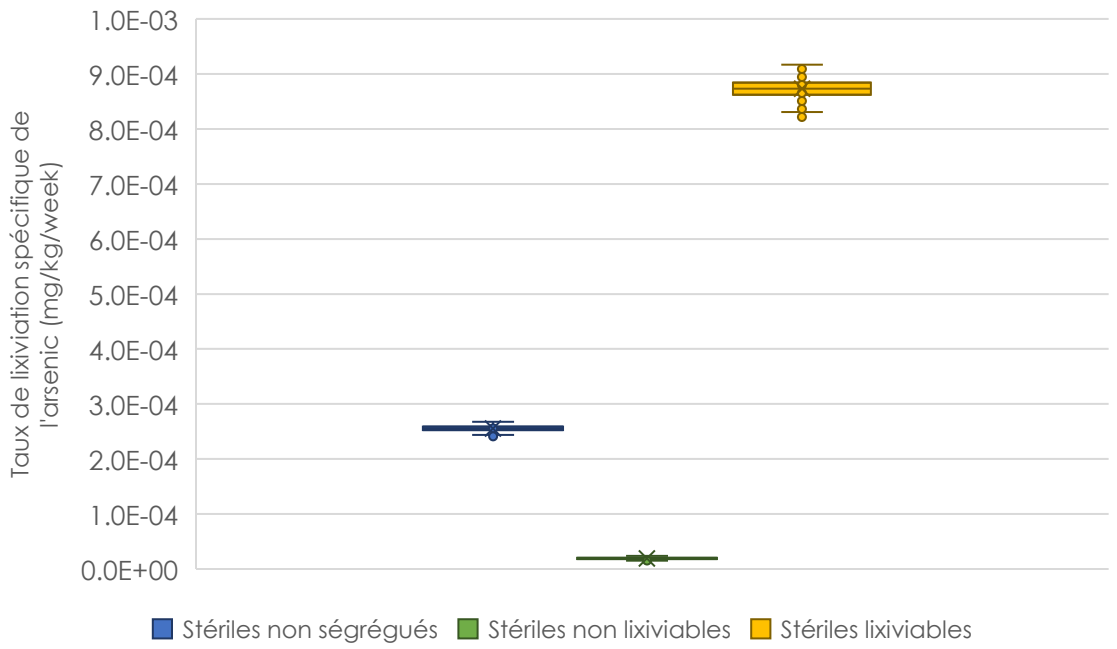

Figure 18. Distribution du taux de lixiviation en vrac de l'arsenic dans les stériles

3.4.2 Tendances modélisées de la concentration en arsenic dans le Stockpile-001

Figure 19 présente la tendance modélisée de la concentration en arsenic au fil du temps à l'emplacement du Stockpile-001. Les résultats de la modélisation de l'arsenic indiquent une augmentation des concentrations entre 2030 et 2036, atteignant un maximum de 0,068 mg/L en moyenne et de 0,085 mg/L dans le cas conservateur (90e centile de 1 000 itérations). La concentration maximale coïncide avec la date estimée d'achèvement de la construction de la halde. Le modèle montre que la concentration d'arsenic diminuera ensuite en dessous de 0,004 mg/l après 2050, tant dans le scénario optimiste que dans le scénario prudent. Selon le modèle, la concentration d'arsenic dans le Stockpile-001 ne devrait pas dépasser le critère MDMER / D019 de 0,10 mg/l pendant l'exploitation.

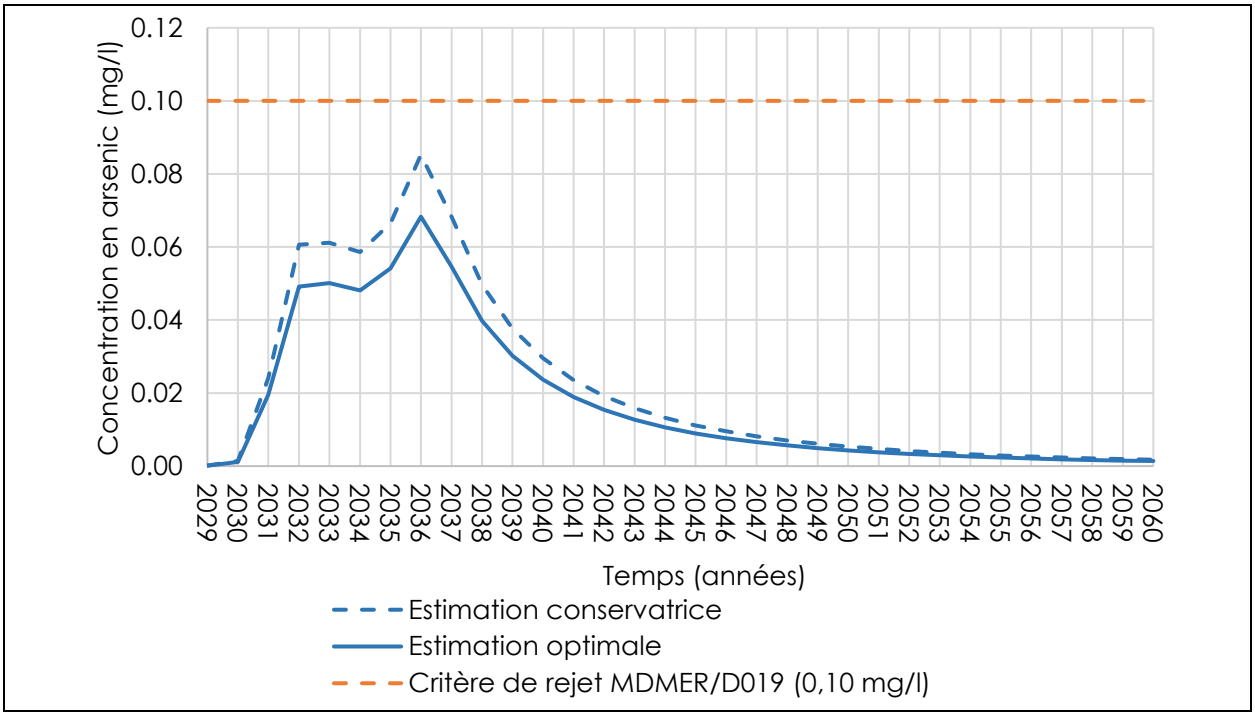

Figure 19. Tendances modélisées de la concentration en arsenic dans le Stockpile-001

3.4.3 Tendances modélisées de la concentration des COPC dans le Stockpile-002

Figure 20 présente les tendances modélisées des concentrations d'antimoine, d'arsenic et de lithium au fil du temps dans les eaux de drainage provenant du site Stockpile-002. Les concentrations d'arsenic (**a**) combinent les résultats des modèles de stériles et de résidus, tandis que pour l'antimoine (**b**) et le lithium (**c**), les résultats du modèle de résidus sont combinés avec des valeurs fixes issues de l'exercice de sélection.

Le graphique indique que les concentrations d'arsenic dans le Stockpile-002 devraient être dominées par la contribution des résidus, avec un maximum de 8,9 mg/L contre 1,8 mg/L pour les stériles. Les concentrations globales devraient augmenter pour atteindre 10,3 mg/L en 2040, ce qui coïncide avec l'achèvement de la partie de la halde dédiée aux stériles. Le modèle prévoit en outre une baisse marquée des concentrations d'arsenic à partir de 2047, avec des valeurs passant sous la barre des 1 mg/L après 2055.

Les concentrations d'antimoine dans le Stockpile-002 devraient être dominées par la contribution des résidus miniers, tandis que la contribution des stériles restera stable à 0,41 mg/L, comme défini lors de la procédure de sélection du COPC. Les concentrations globales augmentent progressivement de 2029 à 2047, pour atteindre un pic de 3,0 mg/L à la fin du placement des résidus. Le modèle prévoit ensuite une baisse marquée des concentrations à partir de 2048, avec des valeurs passant sous la barre des 0,70 mg/L après 2055.

Les concentrations de lithium dans le Stockpile-002 devraient être dominées par la contribution des résidus miniers, tandis que la contribution des stériles restera négligeable, à environ 0,08 mg/L, comme défini lors de la procédure de sélection du COPC. Les concentrations globales

augmentent régulièrement de 2029 à 2035, pour atteindre un maximum de 2,2 mg/L pendant la période de mise en place des résidus. Les concentrations restent ensuite relativement stables jusqu'en 2047, après quoi le modèle prévoit une baisse prononcée à partir de 2048 et une stabilisation autour de 0,10 mg/l après 2055.

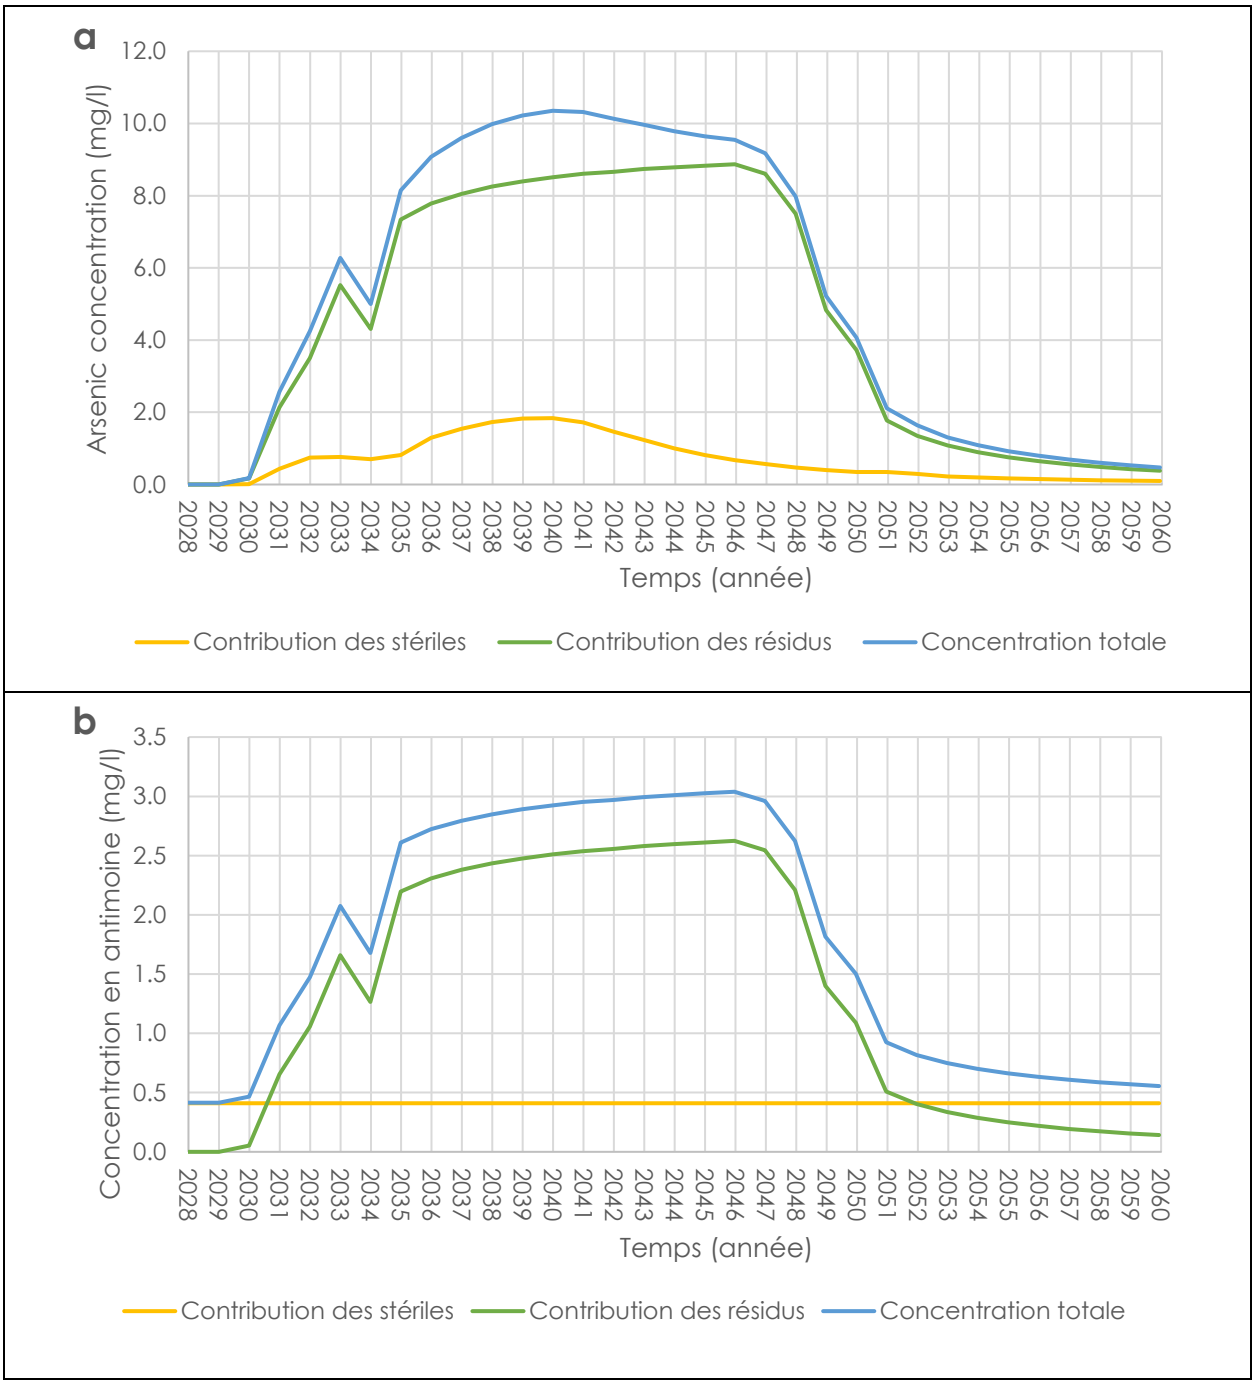

Figure 20. Modélisation des concentrations en COPC dans le Stockpile-002 (1 sur 2)

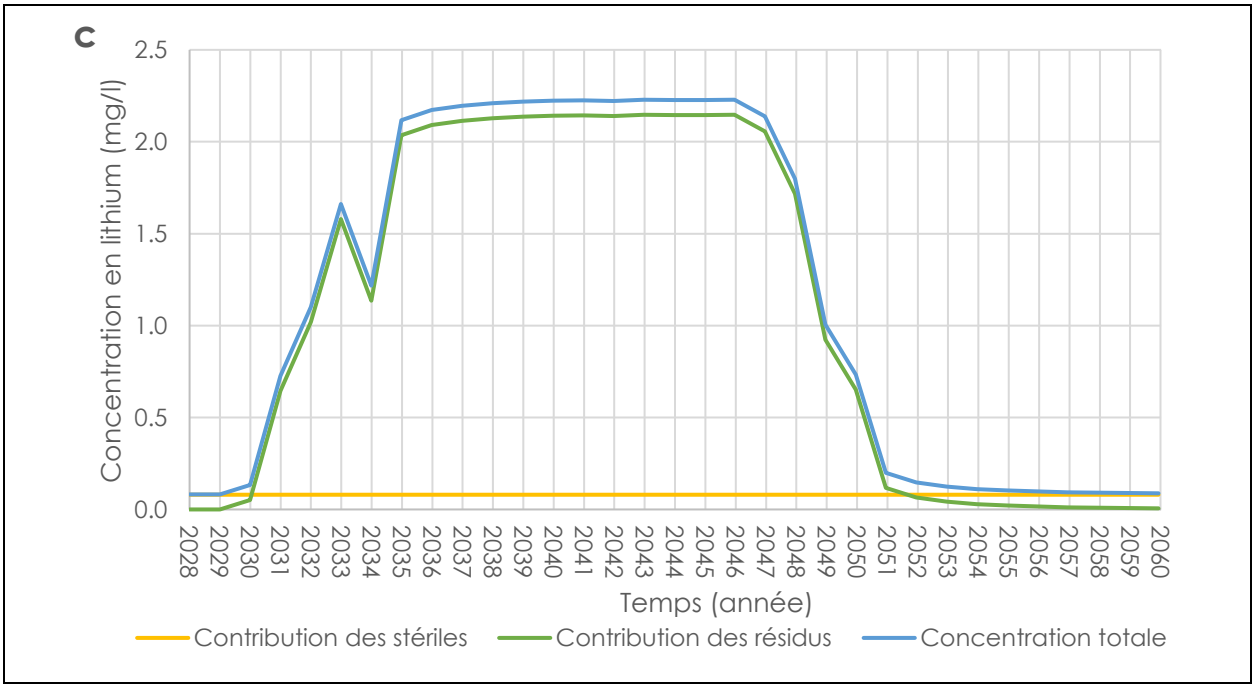

Figure 21. Modélisation des concentrations en COPC dans le Stockpile-002 (1 sur 2)

3.5 Limites du modèle

L'interprétation des résultats de la modélisation doit être considérée à la lumière des incertitudes et des hypothèses inhérentes à l'approche. La fiabilité des concentrations de COPC prévues dépend fortement de la qualité et de la représentativité des paramètres d'entrée utilisés. Comme pour tout modèle géochimique, la précision des résultats ne peut dépasser le niveau de confiance dans les données d'entrée.

L'une des sources d'incertitude les plus importantes réside dans l'utilisation des facteurs d'échelle. Les concentrations de COPC modélisées sont très sensibles à ces paramètres et réagissent de manière directement proportionnelle (**Équation 4**). Par exemple, une surestimation d'un facteur d'échelle donné d'un facteur deux entraînerait des concentrations prévues qui ne représenteraient que la moitié de celles observées dans les conditions réelles. Afin d'atténuer cette incertitude, les facteurs d'échelle ont été sélectionnés avec le plus grand soin et des valeurs prudentes ont été appliquées. Néanmoins, des essais cinétiques futurs, notamment des essais sur colonnes de stériles et des expériences sur le terrain avec des barils, seront réalisés afin d'affiner ces paramètres et de réduire l'incertitude.

Une autre limite des efforts de modélisation actuels réside dans l'omission des mécanismes de sorption potentiels qui peuvent influencer la solubilité et la mobilité de certains COPC. On sait que des éléments tels que l'arsenic et l'antimoine interagissent avec les phases de fer et d'aluminium, ce qui peut agir comme un processus d'atténuation naturel. Comme ces mécanismes n'ont pas été explicitement pris en compte, les résultats du modèle représentent un scénario prudent, dans lequel on suppose qu'aucun contrôle de ce type ne se produit. Une fois encore, des données expérimentales supplémentaires issues d'essais en colonne et sur le terrain

seront essentielles pour améliorer la compréhension de ces mécanismes et les intégrer dans les futures itérations du modèle.

Une autre simplification réside dans le traitement des processus hydrologiques. Le modèle actuel suppose que tous les constituants lessivés sont immédiatement exportés du système dès leur génération. En réalité, l'eau contenue dans la halde peut avoir des temps de séjour importants, ce qui entraîne le stockage, le mélange et la libération retardée des constituants dissous. Cela aurait pour effet d'atténuer les concentrations maximales tout en prolongeant le signal de libération sur une période plus longue, les quantités totales (c'est-à-dire l'aire sous la courbe concentration-temps) restant approximativement constantes. Un tel comportement pourrait influencer considérablement les concentrations maximales à court terme et les charges à long terme, et souligne l'importance de coupler les modèles géochimiques de terme source avec les modèles de transport hydrologique dans les travaux futurs. Cependant, comme elle atténue les concentrations maximales, l'approche de modélisation actuelle est considérée comme conservatrice.

3.6 Criblage des COPC

Une analyse COPC a été réalisée afin d'identifier les composants potentiellement préoccupants susceptibles de s'échapper de Stockpile-001, Stockpile-002 et de la halde de minerai. Le processus a intégré les résultats des essais statiques, des essais cinétiques et de la modélisation géochimique afin d'affiner progressivement la compréhension des rejets potentiels de contaminants.

La sélection s'est déroulée en trois étapes :

1. Les données d'essais statiques ont d'abord été utilisées pour établir une liste initiale de COPC en fonction des concentrations totales et lixiviables.
2. Cette liste préliminaire a ensuite été affinée à l'aide des résultats des essais cinétiques, qui ont permis de mieux comprendre l'évolution temporelle et les taux de libération des éléments dans des conditions contrôlées.
3. Enfin, des simulations de modélisation géochimique ont été réalisées pour les COPC restants afin de quantifier davantage et de limiter les concentrations prévues dans des conditions représentatives du site.

3.6.1 Criblage des COPC par essais statiques

Un effort de criblage COPC a été réalisé sur la base des résultats SPLP et CTEU-9, en utilisant le 90e centile de chacun des constituants identifiés par type lithologique, pondéré en fonction de leurs proportions respectives calculées dans Stockpile-001 et Stockpile-002 **Section 2.9.5**. En ce qui concerne la halde de minerai, les concentrations du 90e centile des constituants mesurées lors des essais de lixiviation effectués sur des échantillons de pegmatite spodumène ont été utilisées.

Le premier examen COPC, réalisé sur la base des résultats des essais statiques, a permis d'identifier l'aluminium, l'antimoine, l'arsenic et le cuivre comme pouvant dépasser le critère CVAA ou MDMER/D019 dans les haldes Stockpile-001, Stockpile-002 et la halde de minerai

(**Tableau 22**). En outre, le fer a également été identifié comme pouvant dépasser le critère dans le Stockpile-001 et la halde de minerai, tandis que le béryllium et le nickel ont été identifiés comme pouvant dépasser le critère uniquement dans la halde de minerai et le Stockpile-002, respectivement. Parmi les constituants mis en évidence dans le cadre des essais, le cadmium, le plomb, le mercure et le zinc sont exclus de la liste des COPC. Il convient de noter que le criblage CTEU-9 est nettement plus conservateur que le SPLP, qui n'a permis d'identifier que l'aluminium pour les trois haldes, en plus de l'arsenic pour le Sotckpile-002.

Certains des COPC identifiés, en particulier l'arsenic, le lithium et l'antimoine, sont connus pour leur grande solubilité, avec peu de limitations dans les conditions d'essai. Le pourcentage de libération dû à la fragmentation et le temps d'agitation sont donc des facteurs clés de leur mobilisation, et l'équilibre est difficile à atteindre. C'est pourquoi les procédures d'essai de lixiviation statique seront dans ce cas de mauvais prédicteurs des concentrations sur le terrain. Les facteurs qui contrôlent la concentration sur le terrain sont principalement influencés par la cinétique et la surface de l'interface de contact entre l'eau et les solides. Dans ce cas, les essais de lixiviation peuvent sous-estimer les concentrations qui seront mesurées sur le terrain.

La solubilité de l'aluminium, du fer, du nickel et du béryllium est principalement contrôlée par le pH, et l'équilibre est plus susceptible d'être atteint dans les essais de lixiviation. L'agitation peut toutefois augmenter artificiellement les concentrations de métaux mesurées en permettant aux colloïdes de passer à travers le filtre de 0,40 µm. Par exemple, l'échantillon VIS-CV5-MS-210 présentait des concentrations en fer CTEU-9 de 22,9 mg/L à un pH de 8,03, bien au-dessus de la solubilité attendue dans les conditions ambiantes (~0,05 mg/L ; $Ksp(Fe(OH)_2) \approx 4{,}87 \times 10^{-11}$ à 25 °C). Un comportement similaire peut se produire pour l'uranium, bien que sa solubilité soit davantage influencée par l'alcalinité et les concentrations de carbonate que par le pH. Dans une halde, la présence de colloïdes dans l'eau devrait être beaucoup moins prononcée, car l'eau se déplace plus lentement et est naturellement filtrée par les matériaux environnants. Les concentrations en métaux devraient toutefois augmenter de manière significative si des conditions de pH acide sont atteintes.

Le protocole d'essai cinétique a été conçu sur la base de ces résultats afin de déterminer si les dépassements identifiés peuvent être confirmés par une analyse cinétique et de dériver des termes sources à utiliser dans un exercice de modélisation.

Tablet. Concentrations de criblage des essais statiques dans Stockpile-001, Stockpile-002 et la halde de minerai

Paramètres	Unité	Critère		Stockpile-001		Stockpile-002		Stock de minerai	
		CVAA	MDMER / D019	SPLP	CTEU-9	SPLP	CTEU-9	SPLP	CTEU-9
aluminium	mg/l	0,28		0,90	2,27	0,54	1,62	0,97	7,04

Plomb	mg/l	0,004	0,08	0,0003	0,0015	0,0002	0,0011	0,0006	0,0017
Lithium	mg/l	0,91		0,09	2,56	0,07	2,12	0,39	10,48
Mercure	mg/l	0,0016		0,00001	0,00001	0,00001	0,00001	0,00001	0,00003
nickel	mg/l	0,067	0,3	0,001	0,003	0,0009	0,0151	0,0007	0,0006
Uranium	mg/l	0,017		0,001	0,027	0,0011	0,0532	0,0025	0,1520
Zinc	mg/l	0,017	0,4	0,003	0,006	0,0024	0,0039	0,0116	0,0088

Les résultats mis en évidence indiquent des valeurs dépassant les critères CVAA ou MDMER / D019.

3.6.2 Criblage des COPC par essais cinétiques

Comme décrit dans la section précédente **Section 3.6.1,** l'antimoine, l'arsenic et le lithium sont des éléments hautement mobiles dont les concentrations dans l'eau en contact avec le matériau ne sont pas directement limitées par le pH ou l'alcalinité. Les résultats des essais statiques peuvent fournir des estimations inexactes qui pourraient conduire à une sous-estimation des concentrations sur le terrain.

La **Figure 22** montre une forte corrélation entre la teneur totale en solides de ces éléments, mesurée à l'aide de la méthode de fusion au peroxyde de sodium à partir de la DHDB développée lors des forages d'exploration, et le taux de lixiviation HCT des échantillons correspondants. En appliquant les coefficients des régressions linéaires (0,0020 pour l'antimoine, 0,0010 pour l'arsenic et 0,1183 pour le lithium) au 90e centile de la teneur en solides mobiles COPC correspondante de la DHDB, il est possible de dériver des taux de lixiviation conservateurs et de les adapter aux conditions sur le terrain à l'aide des facteurs décrits dans la section 2.9.3 « Conception du modèle » du présent rapport.

Les données cinétiques ont également été utilisées pour affiner le criblage COPC des constituants soumis à des mécanismes de contrôle de la solubilité, tels que les métaux de base (aluminium, béryllium, cadmium, cuivre, fer et nickel) et l'uranium. Les estimations de la solubilité de ces COPC ont été calculées pour des conditions neutres et pour des conditions acides dans le cas du Stockpile-002, où doivent être stockés des matériaux PAG dont la teneur en soufre est supérieure à 0,3 % :

Pour les conditions neutres, les concentrations en métaux de base ont été estimées à l'aide du 90e centile des résultats HCT pour chaque constituant identifié par lithologie, pondérés en fonction de leur abondance respective dans la halde correspondante.

Dans des conditions acides, les concentrations ont été calculées à partir des valeurs maximales de HCT, ajustées par un facteur de 20 (équivalent à une division par 0,05) afin de tenir compte du rapport liquide/solide, estimé à environ 5 % dans le Stockpile-002. Cette approche reflète les différents contrôles sur la libération des métaux : dans des conditions neutres, les concentrations sont principalement régies par le pH, largement indépendant du rapport liquide/solide, tandis que dans des conditions acides, la cinétique de la réaction et la surface de contact entre l'eau et les solides deviennent les facteurs limitants, justifiant l'ajustement appliqué.

Le **Tableau 23** résume les résultats de l'effort de criblage affiné mené à partir des données cinétiques et met en évidence les constituants dépassant les critères CVAA/MDMER pour chaque halde. Pour le Stockpile-001 dans des conditions neutres, l'arsenic (ratio 2,24) est le seul constituant dépassant clairement le critère, le cuivre, le cadmium et l'antimoine restant en dessous de leurs limites respectives. Dans le Stockpile-002 dans des conditions acides, l'arsenic (22,4), le cuivre (10), le nickel (4,3) et l'uranium (22) dépassent tous leurs critères, ce qui indique une mobilité potentielle plus élevée de ces éléments dans cette halde, tandis que l'aluminium, le béryllium, le cadmium, le fer, le lithium et l'antimoine restent en dessous de leurs seuils. Pour la halde de minerai, l'arsenic (30,8), l'antimoine (11,0) et le lithium (11,5) dépassent leurs critères respectifs dans des conditions neutres, tandis que les autres métaux se situent dans des limites acceptables. Ces résultats indiquent que l'arsenic dépasse systématiquement les critères de

sélection dans toutes les haldes, l'uranium, le cuivre, le nickel, l'antimoine et le lithium dépassant les limites dans certaines haldes et pour des conditions spécifiques.

Lithium	mg/l	0,91	0,08	0,085	0,0818	0,090	0,08	0,09	10,48[2]	11,5
nickel	mg/l	0,067	0,007	0,11	0,0184	0,27	0,29	4,3	0,0005	0,01
Uranium	mg/l	0,017	0,002	0,09	0,38	22	0,38	22	0,0116	0,68

Les résultats mis en évidence indiquent des valeurs dépassant les critères CVAA ou MDMER/D019.

[1]La valeur la plus conservatrice a été sélectionnée parmi les deux critères (CVAA pour l'aluminium, le cadmium, le cuivre et le nickel ; MDMER pour le fer).

[2]Ces concentrations sont basées sur les essais CTEU-9 et n'ont pas été mises à jour à l'aide des résultats des essais cinétiques, car les informations sur les caractéristiques de la halde de minerai n'étaient pas disponibles au moment de la rédaction du présent rapport.

3.6.3 Sélection finale

Une modélisation géochimique a été réalisée afin de prédire les concentrations dans l'eau de contact des COPC associés aux stériles et aux résidus miniers qui ont été identifiés lors des essais statiques et cinétiques effectués sur les Stockpiles-001 et -002. Plus précisément, l'évolution des concentrations d'arsenic a été modélisée pour le Stockpile-001, tandis que l'évolution des concentrations d'antimoine, d'arsenic et de lithium a été modélisée pour le Stockpile-002. Les résultats de l'effort de criblage des COPC intégrant les essais statiques, les essais cinétiques et les résultats de la modélisation géochimique en termes de concentrations maximales prévues sont résumés dans **Tableau 24**.

Les résultats de la modélisation indiquent que la mise en œuvre d'un protocole de ségrégation, impliquant la séparation complète des lithologies ultramafiques et de tous les matériaux dont la concentration en arsenic est supérieure à 30 ppm, devrait permettre de maintenir les concentrations en arsenic dans le drainage du tas en dessous des critères CVAA et MDMER/D019. À l'inverse, des conditions de lixiviation ont été identifiées pour le Stockpile-002, avec des concentrations d'arsenic dépassant les critères MDMER/D019 jusqu'à deux ordres de grandeur, principalement en raison de la contribution des résidus. De même, l'antimoine et, dans une moindre mesure, le lithium, devraient être lessivés du Stockpile-002, également sous l'influence importante des résidus. L'eau provenant du Stockpile-002 devra être gérée activement afin d'empêcher que des concentrations potentiellement nocives ne se répandent dans l'environnement par rejet ou résurgence.

Le statut réglementaire des différents tas de roches qui soutiennent les mesures de gestion de l'eau prévues dans la conception technique du site est résumé dans **Tableau 25**.

Table 23. Résumé des estimations de concentration maximale de COPC dans les eaux de drainage provenant des Stockpile-001, Stockpile-002 et de la halde de minerai.

Paramètres	Unité	CVAA / MDMER[1]	Stockpile-001		Stockpile-002				Halde de minerai

Code couleur : jaune = essais statiques ; vert = essais cinétiques ; bleu = modélisation des haldes.

Texte en gras : les concentrations dépassent les critères CVAA/MDMER.

[1]La valeur la plus conservatrice des deux critères (CVAA pour l'aluminium, le cadmium, le cuivre et le nickel ; MDMER pour le fer).

Table 24. Composition et classification des haldes

Caractéristique	Stockpile-001	Stockpile-002		Stock de minerai
Rejets miniers	Roche stérile	Roche stérile	Résidus miniers	Minerai
Masse totale (Mt)	44,2	80,6	54,0	Non déterminé
Classification	**Non-PAG/Non-ML**	PAG/ML	Non-PAG/ML	**Non-PAG/ML**
		PAG/ML		
Classification D019	**Faible risque**	**Acidogène/Lixiviable**		**Lixiviable**

Les capacités de stockage des haldes ont été fournies par Atkins, et les quantités par lithologie ont été déterminées sur la base du calendrier d'exploitation fourni par G Mining.

4.0 Conclusion

Les travaux géochimiques présentés dans ce rapport correspondent à un programme de caractérisation géochimique par étapes, comprenant des essais statiques, des essais cinétiques et une modélisation prédictive, entrepris afin d'appuyer la conception du projet au stade de la faisabilité. L'intégration de ces méthodes a fourni une base solide pour comprendre le comportement géochimique des principaux rejets miniers et pour anticiper leurs impacts environnementaux potentiels. La conclusion suivante résume les principaux résultats de ce programme et décrit les prochaines étapes nécessaires pour affiner les prévisions géochimiques à mesure que le projet avance.

Les résultats ABA ont indiqué que 28,2 % des stériles, 88,0 % du minerai (pegmatite spodumène) et 77,8 % des résidus pouvaient être classés comme non PAG en raison d'une teneur totale en soufre inférieure à 0,04 %. Dans l'ensemble, 26,7 % des échantillons de stériles ont été classés comme PAG, dont 12,5 % d'amphibolite (n = 16), 35,6 % de métasédiments (n = 36), 3,0 % de pegmatite stérile (n = 1) et 5,6 % d'ultramafique (n = 3). En revanche, le minerai (pegmatite spodumène) et les résidus ne représentaient que 4,0 % des échantillons PAG. Tous les échantillons de résidus ont été classés comme non PAG.

Sur la base de l'analyse des données ABA, il a été recommandé de séparer les matériaux dont la teneur totale en soufre dépasse 0,3 % et de les placer dans le Stockpile-002, concevant ainsi le Stockpile-001 qui est classé comme Non-PAG/Non-ML (classification D019 : faible risque).

L'analyse du contenu extractible à l'eau régale a permis d'identifier un large éventail de constituants enrichis par rapport à la concentration de fond de la province géologique supérieure, mettant en évidence l'arsenic comme le constituant le plus couramment enrichi, avec 79,4 % des échantillons dépassant la concentration de fond. Les autres constituants identifiés sont le cuivre (40,8 % de dépassements) et le nickel (30,9 % de dépassements).

Les essais de lixiviation SPLP et CTEU-9 ont partiellement reflété les enrichissements mesurés lors des extractions à l'eau régale, mettant en évidence des constituants similaires. Ces procédures de lixiviation ont permis d'identifier les risques potentiels de lixiviation associés à l'aluminium, l'antimoine, l'arsenic, le cuivre, le nickel, le lithium et l'uranium dans les stériles, le minerai et les résidus miniers. Cependant, aucun des 350 échantillons environnementaux testés ne présentait de caractéristiques « à haut risque » selon la classification D019.

Les essais cinétiques comprenaient la poursuite de 15 essais en cellule d'humidité (HCT, plus un duplicata) sur les stériles et le minerai, et le lancement de 5 essais en colonne (plus un duplicata) sur les résidus. Les résultats des essais cinétiques ont été utilisés pour affiner le criblage COPC, ce qui a permis d'écarter ou de confirmer les risques potentiels de lixiviation. Il convient de noter que les résultats indiquent que si des conditions acides venaient à se développer dans le Stockpile-002, les métaux de base, notamment l'aluminium, le cuivre et le nickel, seraient susceptibles de se lixivier. En outre, les essais en colonne sur les résidus ont montré que des dépassements des limites d'arsenic, d'antimoine et, dans une moindre mesure, de lithium pourraient être attendus dans le Stockpile-002.

La modélisation géochimique des haldes a été réalisée à l'aide de données cinétiques adaptées aux conditions sur le terrain et associées à une distribution aléatoire des caractéristiques des stériles tirées de la DHDB (4 678 échantillons de stériles). Les modèles ont été conçus pour prédire les concentrations de COPC dans les eaux de contact des stériles et des résidus miniers des Stockpiles-001 et -002, afin de faciliter la conception du Stockpile-001 avec des stériles non PAG/non ML (classification D019 : faible risque) et d'éclairer la conception du Stockpile-002 et du système de traitement des eaux associé.

Les résultats de la modélisation indiquent que la mise en œuvre d'un protocole de ségrégation, plus précisément la séparation complète de la lithologie ultramafique et l'élimination de tous les matériaux dont la concentration en arsenic est supérieure à 30 ppm, devrait empêcher la lixiviation de l'arsenic au niveau de Stockpile-001, maintenant ainsi les concentrations en arsenic en dessous des critères CVAA et MDMER/D019. À l'inverse, des conditions de lixiviation ont été identifiées dans le Stockpile-002, avec des concentrations en arsenic dépassant les critères MDMER/D019 jusqu'à deux ordres de grandeur, principalement en raison de la contribution des résidus. De même, l'antimoine et, dans une moindre mesure, le lithium devraient s'échapper du Stockpile-002, en grande partie à cause des résidus.

4.1 Recommandations et poursuite des essais géochimiques

La modélisation des haldes présentée dans ce rapport est basée sur les informations actuellement disponibles au moment de la soumission de l'étude de faisabilité. Cette étude a intégré des essais statiques, des essais cinétiques et une modélisation géochimique afin de déterminer les concentrations maximales de COPC dans les Stockpiles-001 et -002 et d'étayer la conception technique des haldes. Comme indiqué à la section 4.7, la fiabilité des concentrations de COPC prévues dépend fortement de la qualité et de la représentativité des paramètres d'entrée. Il est donc recommandé de continuer à recueillir des données géochimiques afin d'affiner les estimations des concentrations maximales de COPC dans les haldes. Une meilleure collecte de données permettra également de réduire l'incertitude du modèle.

Les sections suivantes résument les essais et analyses géochimiques recommandés et continus visant à améliorer la compréhension des risques géochimiques associés aux rejets miniers sur le site.

4.1.1 Essais en barils de terrain

Cinq FBT ont été préparés à partir de stériles provenant de carottes prélevées pendant la phase d'exploration du projet. La sélection des carottes s'est faite en fonction du type lithologique ainsi que de la teneur en arsenic et en soufre. Les carottes sélectionnées ont été expédiées au laboratoire de l'URSTM, où elles ont été broyées à une granulométrie d'environ 5 cm (~2 pouces), homogénéisées et préparées par le personnel de l'URSTM avant la construction des barils. Chaque FBT a été rempli de 200 kg de stériles secs, placés sur une couche de 30 kg de sable siliceux à la base du baril afin de favoriser le drainage. Les barils ont été mis en place sur le site en octobre 2025. Les identifiants des FBT et les stériles correspondants sélectionnés pour mettre en place les essais sont résumés dans **Tableau 26**.

Table 25. Inventaire des FBT construits et lithologie et types de matériaux correspondants

# FBT	Lithologie et type de matériau
CV5-AMP-FBT	Stériles amphibolitiques contenant des concentrations d'As et de S représentatives des caractéristiques du pit shell
CV5-MS-FBT	Stériles métasédimentaires contenant des concentrations d'As et de S représentatives des caractéristiques de la fosse.
CV5-PEG-FBT	Stériles de pegmatite contenant des concentrations d'As et de S représentatives des caractéristiques de la fosse.
CV5-UM-FBT	Stériles ultramafiques contenant des concentrations d'As et de S représentatives des caractéristiques de la fosse
CV5-CP-FBT	Matériau composite de stériles reflétant la composition prévue du Stockpile-001, destiné à servir de FBT de confirmation.

4.1.2 Essais en colonne confirmatoires sur les matériaux de Stockpile-001

Les résultats de modélisation issus de cette étude ont permis d'élaborer un protocole de séparation opérationnel axé sur la séparation des stériles PAG/ML des stériles non PAG/non ML, afin de constituer une halde non PAG/non ML (c'est-à-dire le Stockpile-001). Il est donc recommandé de lancer un essai sur colonne drainée et immergée composé de la proportion lithologique du Stockpile-001, associé aux valeurs limites d'As et de S. La colonne sèche représentera le Stockpile-001 et la colonne immergée représentera le remblayage de la mine à ciel ouvert avec les stériles du Stockpile-001. L'objectif de ces essais sur colonne est de valider les résultats de modélisation du niveau de faisabilité déterminés dans cette étude. Les matériaux de stériles pour ces essais sur colonne ont été préparés et les essais devraient débuter à l'automne 2025.

4.1.3 Remblayage de la fosse avec les matériaux PAG de Stockpile-002

Le concept consistant à remettre les matériaux PAG dans la fosse a été abordé dès le début de l'étude de faisabilité. À l'époque, ce concept n'avait pas été jugé viable en raison de la présence potentielle de réserves supplémentaires de minerai de lithium sous l'enveloppe actuelle de la fosse, laissant ainsi ouverte la possibilité d'exploiter ces réserves à l'avenir. Vers la fin de l'étude de faisabilité, le concept consistant à remblayer la fosse avec des stériles a été réintroduit. Comme indiqué à la section 5.1.2, il est recommandé de procéder à des essais afin d'évaluer les risques de lixiviation des métaux pour les matériaux du Stockpile-001 dans des conditions saturées. Cependant, dans le cadre du même programme, il est également recommandé d'isoler et de tester les matériaux classés comme PAG (teneur en soufre > 0,3 % en poids) du Stockpile-002 afin d'évaluer la viabilité du stockage dans la fosse.

4.1.4 Analyse comparative entre HCT et les essais en colonnes de l'UQAT

Dans le cadre d'une initiative de recherche, l'UQAT a lancé des essais en colonne à partir d'échantillons composites provenant du programme HCT sur les stériles. Une fois les programmes d'essais en colonne et HCT terminés, il est recommandé de procéder à une analyse

comparative entre les essais en colonne sur les stériles et les essais HCT afin de mettre à jour les données d'entrée du modèle et d'étayer les prévisions du COPC pour le Stockpile-001.

4.1.5 Essais sur les matériaux de remblayage des résidus miniers

En raison de la conception hybride de la mine avec des travaux souterrains, Paterson & Cooke a mené une étude sur les matériaux de remblayage des résidus miniers adaptés au site. Les essais sur les échantillons de remblayage issus d'une période de durcissement de 180 jours devraient débuter à l'automne 2025 afin de réaliser des essais statiques et cinétiques visant à étudier les risques de lixiviation des métaux pour le stockage souterrain à long terme.

4.1.6 Modèle cinétique de qualité de l'eau dans les fosses

Les résidus miniers restants après que les capacités des stockages de Stockpile-001 et Stockpile-002 auront été atteintes seront stockés de manière permanente dans la fosse. Il est donc recommandé de développer un modèle prédictif de transport réactif afin de simuler la réponse potentielle de la qualité de l'eau de la fosse au stockage en eau des résidus miniers. Le modèle devrait être conçu comme un système hydrodynamique-géochimique couplé capable de prédire l'évolution des concentrations de COPC (par exemple, l'arsenic, l'antimoine) dans la colonne d'eau recouvrant les stériles submergés.

Un bilan hydrique dynamique doit être intégré afin de tenir compte de la dilution due aux précipitations et au ruissellement, ainsi que du débit sortant par le déversoir. Les termes sources géochimiques cinétiques utilisés comme données d'entrée du modèle doivent être dérivés des résultats mis à l'échelle des essais en colonne immergée réalisés sur des matériaux de stériles représentatifs de ceux qui devraient être placés dans la fosse.

Cet effort de modélisation devrait viser à soutenir l'évaluation des risques potentiels associés au stockage en eau des stériles, à estimer les délais pendant lesquels ces risques peuvent se concrétiser et à éclairer la conception de mesures d'atténuation appropriées.

Extraction Fluid #1 - pH 4.93 ± 0.05
5.7mLs of acetic acid plus 64.3 mLs of 1.0N NaOH bulked to 1L with deionized water.

Extraction Fluid #2 - pH 2.88 ± 0.05
5.7 mLs of acetic acid bulked to 1L with deionized water.
